**Fig. 9.36** Inversion of dispersion curves; the four frames from left to right: 1) black line: mean dispersion curve with error bars, colored lines: forward computation of dispersion curves for ensemble of final models colored according to misfit; 2) black line: H/V ratio at central array station, colored lines: forward computation of H/V ratios for ensemble of final models; 3) P-wave velocity profile for ensemble of final models; 4) S-wave velocity profile for ensemble of final models, note high uncertainty of both P- and S-wave velocities below strong impedance contrast (figures produced using the dinver software; Wathelet et al., 2004; Wathelet, 2008).

Uncertainties in the phase velocity estimates may arise due to data recording, data processing, and the nature of the ambient vibration wavefield (Jongmans et al., 2005; Bonnefoy-Claudet et al., 2005). The main source of uncertainties is a relative arrival time error between sensor pairs due to instrumentation, phase determination, and violation of the plane wave signal. Time shifts may be either systematic or random (Jongmans et al., 2005). Systematic time shifts are caused by, e.g., unlocked GPS time synchronization, internal clock drifts of digitizers, station positioning errors, differences between phase delays of individual sensors caused by variations of seismometer constants and can be prevented by using only well-calibrated sensors in a sufficient number (at least 5, see Jongmans et al., 2005) having a corner frequency well below the frequency band of interest. For ambient vibration

measurements, the magnitude of random time shifts depends on the energy ratio between coherent versus non-coherent wavefield components (analogue to the SNR). The influence of random time shifts can be reduced by using long analysis windows (25-50 times the center period) in a large number. Additionally, in case of curved wavefronts, predictable time delays will distort the slowness estimate (Almendros et al., 1999) which means that nearby sources must be avoided ( $d/r < 2.5$ ; Jongmans et al., 2005).

Although wavefronts arriving at an array with aperture  $A$  from sources located at distances  $d \gg A$  are nearly plane as compared to the more curved wavefronts from closer sources (the presence of plane wavefronts is a basic assumption for the  $f$ - $k$  analysis), phase velocity curves derived from distant sources may show poor quality due to a lack of coherent energy attributed to the intrinsic attenuation properties of the medium (Jongmans et al., 2005). In addition, for strongly attenuating structures, higher mode energy contributions may dominate for certain frequency bands resulting in jumps of the estimated phase velocity between fundamental and higher mode branches, and intermediate phase velocities for comparable energy levels between different modes of propagation (for description and treatment of "apparent phase velocities", see Tokimatsu et al., 1992; Tokimatsu, 1997).

At sites having a sharp impedance contrast in the subsurface, spectral energy holes in the waveform spectra of the vertical component can be observed at least around the resonance frequency due to the filter characteristics of the subsurface hindering or impeding the determination of the dispersion curve in this frequency range (Scherbaum et al., 2003; Jongmans et al., 2005).

## 9.11 Array design for the purpose of maximizing the SNR gain

Signal detection at array stations is governed by the gain that can be achieved in the signal-to-noise ratio (SNR) through the process of beamforming. This subsection provides some guidance as to how an array can be designed to maximize this gain. Other aspects of array design (e.g., slowness resolution) have been dealt with elsewhere in this chapter.

### 9.11.1 The gain formula

The SNR gain  $G$  by beamforming achievable from seismic array data can be expressed by

$$G^2 = \frac{\sum_{ij} C_{ij}}{\sum_{ij} \rho_{ij}} \quad (9.27)$$

where  $C_{ij}$  is the signal cross-correlation between sensors  $i$  and  $j$  of an array and  $\rho_{ij}$  is the noise cross-correlation between sensors  $i$  and  $j$  (see also Section 9.4.5). For an array with  $M$  sensors, this formula collapses to the well-known relation  $G^2 = M$  for perfectly correlating signals ( $C_{ij} = 1$  for all  $i$  and  $j$ ) and uncorrelated noise ( $\rho_{ij} = 0$  for  $i \neq j$  and  $\rho_{ij} = 1$  for  $i = j$ ).

For any array geometry it is thus possible to predict the array gain if the signal and noise cross-correlations are known for all pairs of sensors of the array layout. The remainder of this subsection describes how to design an array based on the availability of such correlation data.

### 9.11.2 Collection of correlation data during site surveys

Correlation data for use in the design phase should be collected in a carefully planned site survey. The sensor layout during the survey should be planned so as to represent as many intersensor distances as possible. The first layout for the experiments eventually leading to the deployment of the 25-element NORES array in Norway in 1984 utilized only 6 sensors, in a rather irregular geometry, as shown in Fig. 9.37.

**Fig. 9.37** The first array layout for the experiments leading to the design of the 25-element NORES array in Norway in 1984.

The deployment for the collection of correlation data should be done in a way as simple as possible and should take advantage of outcropping bedrock where possible. The layout should preferably comprise ten sensors or more. If, however, for example only six sensors are available for the site survey, one could start out with a configuration something like that in Fig. 9.37 and record data continuously for about one week. At the end of this one-week period, one could redeploy four of the sensors and record data for another week. Two of the sensors would then occupy the same locations for the entire two-week recording period and would provide evidence (or lack thereof) of consistency in the results between the two one-week periods. The largest intersensor separation represented in these data should be, if possible, of the order of 3 km.

The experience from the design of the NORES array showed that the signal and noise correlation curves obtained from the early experiments (with six, and later twelve sensors) possessed most of the characteristic features (Mykkeltveit, 1985) and thus qualitatively resembled the curves derived later on from configurations comprising many more sensors (up to 25).

### 9.11.3 Correlation curves derived from experimental data

In the processing of the data from the site survey, cross-correlation values must be computed for all combinations of sensor pairs of the experimental layout. Consider, for example, a geometry of six sensors. This geometry comprises 15 unique pairs of sensors. Consider also a short interval of say 30 seconds of noise data (make sure no signal is contained in this time window) and compute the cross-correlation values for each of the 15 unique pairs of sensors (no time shifts are to be introduced for this computation). The time series are first bandpass filtered so as to derive the correlation values of one particular frequency (or frequency band). The 15 correlation values are then plotted in an x-y diagram, where the x-axis represents the intersensor separation and the y-axis the correlation value (between -1.0 and +1.0), resulting in a plot as shown in Fig. 9.38.

**Fig. 9.38** Noise cross-correlation values for a test layout of 6 sensors.

When plotting the cross-correlation values as a function of sensor separation only and thus disregarding possible directional dependencies, an implicit assumption is made of azimuthal symmetry in wavenumber space, over a longer time interval. This assumption is justified by the NORES experience, which shows that only a relatively small scatter is exhibited in the correlation data.

Computations of the kind described above should also be done for signals, which for the purpose of this section will be assumed to be P waves (although design strategies for the detection of S-type phases will be similar to those described here). A recording period of about 14 days during the site survey hopefully should be sufficient to record a reasonable number of representative P-wave arrivals. The time windows for these computations should be relatively short (approximately 5 seconds) to capture the coherent part of the signal arrival. Signal time series must be aligned in accordance with the signal slowness (phase velocity and direction of approach) before the cross-correlation is computed. Again, the time series must be filtered in a relatively narrow band around the peak frequency of the signal being considered. A plot like the one shown in Fig. 9.39 results from this, again assuming a six-sensor layout with 15 unique combinations of sensor pairs.

**Fig. 9.39** Schematic plot of P-wave cross-correlation values for a test layout of 6 sensors.

Computations as described above should be repeated for various time intervals for the noise, and for various P arrivals recorded during the site survey. Then, for each frequency interval of interest, all data (both noise and signal correlation data) should be combined in one diagram for the purpose of deriving curves (based on interpolation) that are representative of that frequency interval, and that provides correlation values for all intersensor separations. Such diagrams might then appear as shown in Fig. 9.40, in which the upper curve represents the signal correlation and the lower curve the noise correlation.

**Fig. 9.40** Schematic plot of signal (upper, green) and noise (lower, blue) correlation curves representing experimental data collected for a test array.

For the noise correlation curve in Fig. 9.40 to be representative for 2 Hz, e.g., the noise data should be filtered in a band where 2 Hz is close to the lower limit of the passband, due to the spectral fall-off of the noise. A passband of 1.8 – 2.8 Hz might be appropriate for the noise, but actual noise spectra for the site in question should be computed and studied before this passband is decided on. To generate a signal correlation curve representative for 2 Hz, signals should be used that have their spectral peaks close to this frequency, and some narrow filter passbands centered on 2 Hz should be applied to the data. These curves would then be used to predict gains for various array designs as detailed below.

It should be noted that the rather pronounced negative minima for the noise correlation curves (as schematically represented in Fig. 9.40) are consistently observed for the NORES array. It is the exploitation of this feature that provides for gains in excess of  $\sqrt{M}$  (see Section 9.4.5 and Eq. 9.7), commonly observed at the NORES array (or sub-geometries thereof). It should also be noted that this feature of negative noise correlation values is not a universal one; e.g., Harjes (1990) did not find consistently such pronounced negative minima for the GERES test array in Germany.

Braun and Schweitzer (2008) investigated the noise correlation behavior for a test-array installation of three-component sensors in Italy and similar intersensor-noise correlations were found for the rotated horizontal components as for the vertical sensors. The noise-correlation lengths (200 m for signals in the 2 – 4 Hz frequency passband) were about half as long as those observed for NORES. In addition, they also found specific BAZ directions with coherent noise with apparent velocities of Rg-type waves, which may be reducible by special array design.

## **9.12 Considerations when planning a new seismic array**

### **9.12.1 Basics**

Earlier in this chapter we described some older but still operational large seismic arrays. Today, with numerous digital seismic stations and the CTBTO monitoring arrays around the world, there is much less need for new arrays focusing on teleseismic monitoring. However, this is not true for small aperture arrays focusing on seismic sources at local and regional distances.

Based on very positive experiences during the last years with NORES-type, small aperture arrays, a recommended approach would be to use such an array geometry when planning a new array. However, it became also clear that an array does not necessarily need to consist of as many sites as NORES with its 25 sites. Quite good slowness (i.e., apparent velocity and backazimuth) estimates can already be achieved with SPITS-type arrays consisting of nine sites (corresponding to the A and B rings of NORES, see Fig. 9.41). The aperture of such a nine-element array should be between 750 and 1500 m depending on the local noise conditions (see Section 9.12.2). Then, even the identification and rough classification of teleseismic onsets is still possible.

With respect to instrumentation, it is no problem to keep the single sensors as broadband as possible. In particular when monitoring stronger events at local or regional distances the recording of higher frequencies in parallel with seismic low frequency energy can be of high importance, e.g., the new SPITS array is equipped with nine broadband, acceleration-proportional sensors, with a flat response between 100 s and 35 Hz.

A general problem of existing arrays is that they all record seismic waves predominantly with the use of vertical sensors only. Thereby, S-phase observation is much more difficult and limited to S phases with strong SV particle movements. This problem, discussed since some time, was partly solved for NORES-type arrays by installing three-component sensors at several sites (e.g., Schweitzer, 1994; Schweitzer and Kværna, 2002; Braun et al., 2004; Gibbons et al., 2011). Today, we can recommend equipping as many array sites as possible with three-component sensors as e.g., is the case for the refurbished Gräfenberg array, which has now three-component sensors at all 13 sites, and SPITS, which is equipped at six of nine sites with three-component sensors (Gibbons et al., 2011).

Finally, we would still like to recommend a central timing system for any array. During the last decades many cases were observed of malfunctioning single clocks at individual array sites, which produced unexpected (and sometimes undetected) wrong slowness results due to small time shifts. If the central clock of an array is showing a wrong time, the absolute onset times of seismic phases may be influenced, but the array itself is still functional.

### 9.12.2 Example: A possible design strategy for a 9-element array

As an example of application of the design ideas outlined above, let us consider practical aspects of the design of a 9-element array. Several new arrays that have been built by the CTBTO for the International Monitoring System (IMS) for CTBT monitoring comprise 9 elements. A useful design for a new 9-element array would be one for which there are 3 and 5 elements equidistantly placed on each of two concentric rings, respectively, plus one element at the center of the geometry, as shown in Fig. 9.41.

The elements on the two rings should be placed so as to avoid radial alignment, which would produce stronger side lobes in the array transfer function as any regular pattern of the array geometry. If the five elements of the outer ring are placed at 0, 72, 144, 216 and 288 degrees from due North, the elements of the inner ring might be placed at 36, 156 and 276 degrees, as shown in Fig. 9.41. Within this class of design, the problem at hand is thus to find the radii of the two rings that for a given site would provide the best overall array gain. To constrain the design options even further, one might consider adopting the NORES design idea, limited to these two rings. The radii of the four NORES rings are given by the formula:

$$R = R_{\min} \cdot 2.15^n, (n = 0, 1, 2, 3) \quad (9.28)$$

For NORES,  $R_{\min} = 150$  m. For the design problem at hand, only  $R_{\min}$ , the radius of the inner ring, remains to be determined from the correlation data, whereas the radius of the outer ring would then be 2.15 times the radius of the inner ring.

**Fig. 9.41** The figure shows a possible design for a 9-element array.

The final step in the procedure outlined here is to compute expected gains for various array designs within this class of geometries. To this end, one must determine which signal frequencies are of the largest importance with regard to the detection capability of the array at the site under study. Assuming that three dominating P-wave signal frequencies,  $f_1$ ,  $f_2$  and  $f_3$ , (e.g., 1.8, 2.5 and 3.5 Hz) have been identified in the preparatory survey, these should be taken into account in the computations to derive the optimum array geometry. We would then

have available from the site survey empirically-based correlation curves in analytical or tabular form that would provide correlation values for **all** intersensor separations of interest. The gains as a function of frequency for various values of the parameter  $R_{min}$  could then be computed using the formula for the array gain and the correlation values derived from the correlation curves, for the relevant intersensor separations. The results of these computations could be tabulated as indicated in the (here artificial) Tab. 9.1. For more details and application of these analysis steps see Mykkeltveit (1985).

Note that for the lowest frequency considered ( $f_1$ ), it might pay in terms of array gain to exclude the elements of the inner ring from the gain computations, since noise correlation values for low frequencies may be high for many sensor pairs involving sensors of relative short intersensor distances (e.g., the innermost sensor rings).

**Tab. 9.1** Example for a table providing gains achievable by beamforming when applying different values of the parameter  $R_{min}$ .

| $R_{min}$ [m] | Gain ( $f_1$ ) [dB] | Gain ( $f_2$ ) [dB] | Gain ( $f_3$ ) [dB] |
|---------------|---------------------|---------------------|---------------------|
| 200           | 3                   | 6                   | 8                   |
| 300           | 4                   | 8                   | 9                   |
| 400           | 5                   | 9                   | 7                   |
| ...           | ...                 | ...                 | ...                 |
| 1000          | 9                   | 7                   | 4                   |
| ...           | ...                 | ...                 | ...                 |

The optimum geometry would correspond to the value of  $R_{min}$  that gives the best overall gain in Tab. 9.1. This judgment would be based on some appropriate weighting scheme for the frequencies considered.

The procedure outlined here could be generalized to a class of designs for which the radii of the two rings are varied independently. Gain values would then be tabulated as shown in Tab. 9.1, but there would now be a sequence of tables (each table would represent a fixed radius of one of the two rings). The search for the optimum geometry would then be performed across all these tables.

## 9.13 Routine processing of array data at NORSAR

### 9.13.1 Introduction

Now, we will explain the main features of the automatic routine processing of data recorded by regional arrays at NORSAR (Fyen 1989; 2001a and b).

As aforementioned in Section 9.2, the array data processing can be divided into three steps:

- Detection Processing (DP), i.e., performing STA/LTA triggering on a number of predefined beams;

- Signal Attribute Processing (SAP), i.e., performing signal feature extraction of detected signals, such as onset times, amplitudes, and frequencies/periods of identified phases; and
- Event Processing (EP), i.e., performing phase association, location processing and event plotting.

In Mykkeltveit et al. (1988) and in Kværna (1989), it is shown that different combinations of sensors, for example, within the NORES array, give different noise reduction for various frequency bands. The lesson is that it is not always optimal to use all seismometers of the array to form a beam; rather one should in general use different sub-configurations, tailored to the signal frequencies.

Fig. 9.16 showed different beams for the same P-wave signal. It is obvious from this figure that we need beams for various slowness vectors to detect the signal.

**Fig. 9.42** The bottom trace shows raw data from instrument A0 at the center of the ARCES array. The next traces from bottom to top are data from the same instrument filtered with 3rd order Butterworth bandpass filters using frequency bands 0.5 – 1.5, 1 – 3, 2 – 4, 4 – 8, 6 – 12, and 8 – 16 Hz, respectively.

We have earlier pointed out the importance of beamforming and filtering for signal enhancement. In the array detection process, several beams are formed, and several different filters are used (see Tab. 9.2). An STA/LTA detector is used on each beam, and as seen from

Fig. 9.17, we may get a trigger on several beams. The detector will compare the maximum STA/LTA (SNR) for every beam within a (narrow) time window. The influence of different filters on the detectability of seismic signals is demonstrated in Fig. 9.42. It shows ARCES data with one of the seismometer outputs filtered in different filter bands. An important point made in this figure is that the regional seismic phases Pn and Lg have their best SNR in different frequency bands. So to be sure to detect both phases, we should use several filter bands in the detector recipe.

**Tab. 9.2** An example for a detection beamset as it was in use at NORSAR for many years for the SPITS array. THR is the SNR threshold used to define a state of detection and “all” means that the whole SPITS array (SPA0, SPA1, SPA2, SPB1, SPB2, SPB3, SPB4, and SPB5) is used to form this beam (from Schweitzer, 1998).

| BEAM NAMES  | VELOCITY [km/s] | BACKAZIMUTH [deg]                          | FILTER        |       | THR | SITES (verticals only)        |
|-------------|-----------------|--------------------------------------------|---------------|-------|-----|-------------------------------|
|             |                 |                                            | bandpass [Hz] | order |     |                               |
| S001        | 99999.9         | 0.0                                        | 0.8 – 2.0     | 4     | 4.5 | SPA0 SPB1 SPB2 SPB3 SPB4 SPB5 |

Thus we have three parameter sets that make up the input for the STA/LTA detector: the specific array configuration, the slowness vector, and the filter band to use for this beam. Note that one could also use just a single seismometer instead of a beam. Based on experiments, a list of these parameters has been compiled at NORSAR that constitutes a “detector recipe” with, e.g., numerous beams using different slownesses, different configurations, and different filter bands. For a large signal, the detector program will trigger on many beams, and the program will use a detection reduction process to report only one detection for each signal.

As an example, a detector recipe listing the entire beam set composed of 254 beams for the online processing of data from the SPITS array, as it was in use at NORSAR for many years, is included in Tab. 9.2. The complete process is illustrated in the following Sections 9.13.2 – 9.13.4 by using a data example from the ARCES array.

### 9.13.2 Detection Processing – DP

The DP process continuously reads data off a disk loop or any other continuous database and uses beamforming, filtering, and the STA/LTA detector to obtain detections (triggers). Thus the DP program produces, e.g., a single file for each array and each day of the year (DOY).

The following list gives some example lines from such a file for DOY 199 in 1996 for the ARCES (ARC) array. The file contains the name of the detecting beam (e.g., F074), the time of detection (199:16.03.49.3), the end of the detection state (199:16.03.53.1), the maximum STA (242.4), the LTA at the time of detection (10.27), the SNR ( $\text{STA}/\text{LTA} = \text{SNR} = 23.601$ ), and the number of beams detecting (37). The detecting beam reported (here F074) is the one beam, normally out of many, that detected this signal with the highest SNR. The key parameters reported are the beam code, the trigger time, and the  $\text{SNR} = \text{STA}/\text{LTA}$ . The beam code (leftmost column in the list below) points to a file (see Fig. 9.43) containing information on beam configuration, slowness and filter used. The format of a detection output is not important. Important is to create a list of detections that can be used for further analysis.

| BEAM | DETECTION TIME           | STA    | LTA   | SNR    | # of BEAMS |
|------|--------------------------|--------|-------|--------|------------|

```

**Fig. 9.43** Example of the contents of a file with the parameters that characterize beam F074. THR is the SNR detection threshold, BF1 and BF2 are the lower and the upper limits of the bandpass filter applied, BMVEL and BMAZI are the apparent velocity and the backazimuth for this beam, REFLAT, REFLON, REFELE, and REFSIT define the reference site of the beam, and SELECTED CHANNELS lists the site configuration.

### 9.13.3 Signal Attribute Processing – SAP

This process sequentially reads detections from the detection file and performs an f-k analysis for each detection to estimate apparent velocity and backazimuth. The estimated velocity and backazimuth is referred to as “observed slowness”. Waveform segments for the analysis are again read from a disk loop or any other database.

A special version of NORSAR’s EP program is used and produces a new file for the ARCES array on day-of-the-year (DOY) (here 199 in 1996). The key parameters reported in the EP-result files are the signal onset time, the beam code, the SNR, the estimated slowness, the signal amplitude and frequency, and the phase identification based on the slowness estimate.

**Fig. 9.44** Example of the contents of a file with the Signal Attribute Processing results for the detections listed in Fig. 9.43.

A few lines from such a file are listed above (Fig. 9.44). The entries are the arrival id number (e.g., 25), the estimated onset time (199:16.03.48.409), the difference time (DT) between trigger and onset time (0.89 s), the beam name (F074), the SNR (23.6), the apparent velocity (VEL in km/s) from f-k analysis (7.4), the preliminary phase name by automatically considering apparent velocity and three-component polarization analysis (Pgn, which is used

here as a code for ‘either Pg or Pn’), the estimated backazimuth (BAZ) from f-k analysis ( $122.5^\circ$ ), the relative power from f-k analysis (0.72, a number between 0.0 (no signal coherency) and 1.0 (perfect signal coherency)), the f-k analysis quality indicator (Q) (2, 1=best, 4=poor), the estimated dominant frequency (FREQ) in Hz (4.85), the maximum amplitude (AMP) in counts (476.9), the maximum STA of the detection (242.4), the polarization analysis classifications IP, IS (0 and  $-3$ , respectively), the polarization analysis rectilinearity (REC) (0.69), the horizontal/vertical ratio (H/V) (0.49), the inclination angle (INC) ( $41.26^\circ$ ), and the polarization angle (POL) ( $73.94^\circ$ ).

Fig. 9.45 shows raw data for the detection reported at time 199:16.03.49.3 (see the detection result listing). The signal attribute process will use this detection time to measure a first onset time of the signal and then to select a 3 second wide time window starting 0.5 second before the preliminary onset time (here 199:16.03.48.4, see also the time window indicated by vertical lines). The data from all vertical seismometers within this time window will then be used for f-k analysis to obtain the true apparent velocity of the signal.

**Fig. 9.45** Raw data from all the vertical seismometers of the ARCES array. The time interval contains the Pn phase of a regional event. The vertical bars define a 3 second time window that is used for the f-k analysis.

The result for the f-k analysis is shown in Fig. 9.46. This process is repeated for all detections and Fig. 9.47 shows the data interval selected for the Lg detection. The corresponding f-k analysis results are shown in Fig. 9.48. In automatic mode, of course, the EP program will not display any graphics. The figures are only produced for illustration purposes. However, the capability of displaying results graphically at any step of a process is essential to be able to develop optimum recipes and parameters. The EP program may output results into flat files or a database.

**Fig. 9.46** Result of the wide-band f-k analysis for the data in Fig. 9.45, pertaining to the Pn-phase interval.

**Fig. 9.47** Raw data from all the vertical seismometers of the ARCES array. The time interval contains the Lg phase of a regional event. The vertical bars define a 3 second time window that is used for the f-k analysis.

**Fig. 9.48** Result of the wide-band f-k analysis for the data in Fig. 9.47, pertaining to the Lg-phase interval.

### 9.13.4 Event Processing – EP

This process sequentially reads all detections from the parameter extraction processing file. Whenever a detection with an apparent velocity greater than, e.g., 6.0 km/s is found, it is treated as P. Additional detections are searched for, and if additional detections are found with backazimuth estimates not more than, e.g., the predefined azimuth range of 30° from the first detection and a detection time not more than 4 minutes from the first detection, they are used as associated detections. If detections with an apparent velocity less than 6.0 km/s are found, then they are treated as S (Sn, Lg). If phases within 4 minutes and backazimuth deviation of less than 30° with a first P and an S later are found, then they are treated as observations from a regional event. A location routine, which uses the backazimuth information, is used to locate the regional event. More details on these topics are given in Mykkeltveit and Bungum (1984). The results are again written in a separate file for each DOY (here 199 in 1996). A few lines from such files are exemplarily listed below:

|    |                |     |      |                                 |        |       |      |       |       |           |

Whenever an event is declared, a location is performed and reported with two lines (**HYP** and **EPX**) that contain event number (10), origin time (199:16.02.51.2), latitude (67.369°), longitude (33.479°), ML (1.01), distance in [km] (404.3), backazimuth (122.7°), fixed depth at 0 km (0F). The associated phases are listed thereafter, and for the Pn phase we have the id number (25), the arrival time (199:16.03.48.4), the station name (FRS, the old, NORSAR-internal code for ARC5), the phase name (PN), the maximum amplitude in [nm] (0.268), the corresponding dominant frequency in [Hz] (4.8), the SNR (23.6), the beam name (F074), the apparent velocity (7.4), the backazimuth (122.5°), and an explanatory code from the location process. **LOCATE** means that this phase was used for locating the event and **ASSOC** means that this onset was associated but not used for the location processing. **Tele** means that this phase is interpreted as a teleseismic onset and **Noplots3ci** means that this phase was not used for any event definition. Such onsets are then also often declared as **nois** (i.e., noise) observations. The “beam-name” **aVG** in a **MAG** line means that the corresponding arrival time is used for measuring the amplitude for **ML** as average amplitude of all traces, and the apparent velocity is the group velocity in that case. The key parameters reported are the origin time, the hypocenter, and the magnitude for each located event, and onset time, amplitude and frequency, SNR, beam code, and apparent velocity for all associated detections.

The example above identifies one group of phases with backazimuth around 123° that are arriving within 4 minutes. The first phase within the group has a regional P-wave apparent velocity, and it is followed by a phase with a regional S apparent velocity. Those are the predefined criteria for defining an event. For each declared event, an event plot may be created (see Fig. 9.49). Results of the automated regional array processing at NORSAR can be found at <http://www.norsardata.no/NDC/bulletins/dpep>.

**Fig. 9.49** Summarizing plot for the above discussed regional event.

### 9.13.5 Event location with a network of arrays

It became very soon obvious that the location precision of single small aperture arrays is quite limited mostly due to scatter in the backazimuth estimates and uncertainties in automatically measuring the travel-time differences between P- and S-type onsets. After building up a network of small aperture arrays in Northern and Central Europe during the late 1980s and early 1990s, a joint interpretation of observations from several small aperture arrays could be tested. One successful approach became the Generalized Beam Forming (GBF) location algorithm. This algorithm, developed at NORSAR, can automatically utilize the results of several seismic arrays in a common bulletin (Ringdal and Kværna, 1989; Kværna et al., 1999). Today, data from the highly sensitive regional arrays ARCES, FINES, HFS, SPITS, and NORES, and the teleseismic NORSAR array (NOA) are automatically processed in on-line mode applying this regional and local event-location process (<http://www.norsardata.no/NDC/bulletins/gbf>). For events observed at several arrays (i.e., events with local magnitudes above 2) these fully automatically achieved GBF locations are usually within a distance of 10 to 50 km from the analyst reviewed event locations (<http://www.norsardata.no/NDC/bulletin/regional/>). However, the location capabilities are very much depending on the relative location of the events to the geometry of the array network and the number of observed phases.

### 9.13.6 Teleseismic event location

Benndorf (1906; 1907) published that in the case of a spherically symmetric Earth model apparent velocities (or the seismic ray parameters) are constant along their whole ray path through the Earth (Benndorf's Law). If the velocities inside the Earth are known, it can easily be shown that the ray parameter of seismic onsets changes with the epicentral distance and that an observed ray parameter (or apparent velocity) can directly be inverted for the epicentral distance.

For modern spherically symmetric Earth models and seismic arrays of at least 10 km aperture, this principle works fine for first arriving P-type onsets from seismic events at teleseismic distances (i.e., from about 25° to about 100° epicentral distance). Events at shorter distances are hard to locate because the derivative of the apparent velocity with respect to distance is very small and triplications of the travel-time curve do not allow for a unique correspondence between apparent velocity and distance. At distances beyond ~90° these derivatives become for P waves again very small and in the Earth's shadow zone for P ( $D > 100^\circ$ ) the interpretation of the different core-phase onsets is also quite difficult and limits the location capabilities of a seismic array. Knowing the epicentral distance, the observed BAZ can then be used to define the epicentral coordinates.

The described event location technique has been in use at least since the 1960s and a quick look in the bulletins of the International Seismological Centre shows the huge amount of reported teleseismic event locations made with, e.g., the Large Aperture Seismic Array (LASA) in Montana, USA, the Yellowknife Array (YKA) in Northern Canada, the Gräfenberg Array (GRF) in Bavaria, Germany, or the large Norwegian Seismic Array (NOA) in southern Norway.

For the large NORSAR array (NOA), we may choose between frequency-domain f-k analysis or the beampacking process. The benefit of using beampacking rather than frequency domain f-k analysis is that for every point in slowness space, we can use time delay corrections (see Section 9.5.4) and obtain a calibrated slowness. On the basis of phase identification and measured slowness, we then get an epicentral distance by screening a slowness table and thereby a location using distance and backazimuth. So, for each detection a corresponding location is provided by NORSAR's near real-time array data processing. All results of the automatic array processing of the NOA array can be found at <http://www.norsardata.no/NDC/bulletins/dpep>.

## **9.14 Seismic arrays in Earthquake Early Warning Systems (EEWS)**

### **9.14.1 Introduction**

The advantage of applying seismic array techniques in EEWS is connected with the capability of an array not only to observe a seismic signal but also to measure its propagation direction and apparent velocity. However, the capability of an array to measure the backazimuth (BAZ) and apparent velocity with sufficient accuracy and to suppress other than the target signals is very much depending on the array geometry and the number of its sensors. Therefore, not each array is equally suitable for an Earthquake Early Warning System (EEWS). Here, we will focus on the usage of seismic arrays as EEWSs in general and in particular on real-time algorithms and discuss the advantages and disadvantages of applying array-analysis techniques as input for any EEWS.

### **9.14.2 Examples for array contributions to fast event locations**

#### **9.14.2.1 Single array results**

As mentioned earlier, it is possible to locate seismic events with data observed by one or more seismic arrays. However, in the case of any fast event location algorithm array analysis can only contribute if the whole data processing is automated. On the other hand, the recorded data volume of seismic arrays is very large, thus also requiring automated data processing techniques. Therefore, array data processing algorithms were as much as possible automated since the 1960s. For example, NORSAR's program package DP/EP as described in Section 9.13 was mostly developed in the 1970s – 1990s and later adapted to many other array installations (Fyen, 1989; 2001a and b).

After international exchange of emails was becoming more reliable and common in the early 1990s, it became possible to report event locations or strong P-phase observations based on fully automatic data processing algorithms. Thereby, results from the NORSAR, YKA, or the GERES array were automatically sent to, e.g., the USGS for its Quick Epicenter Determinations (QEDs), the European-Mediterranean Seismological Center (EMSC), the Swiss Seismological Service (SED), and the wider interested seismological community.

#### **9.14.2.2 The Fast Earthquake Information Service (FEIS) algorithm**

At the University of Bochum a special alert system was developed in the mid 1990s, which combined the mentioned single array observations with recordings of the newly at that time installed German Regional Seismological Network (GRSN). The so-called Fast Earthquake Information Service (FEIS) algorithm (Schulte-Theis et al., 1995; Harjes et al., 1996) was triggered by strong local or regional events observed by the GERES array. For this, the data of the regional GERES array were automatically analyzed in real time by applying the DP/EP array software developed at NORSAR (Fyen, 1989; 2001a and b, see also Section 9.13). After each automatic GERES location with a local magnitude above 3, the FEIS algorithm was triggered, consisting of the following steps:

- recalculation of an initial location from the GERES data alone;
- calculation of theoretical onset times for regional phases (Pn, Pg, Sn, Sg) at all GRSN stations;
- polling of all automatic GRSN-detection lists via telecommunication lines for a larger time interval around the assumed arrival times;
- searching a small time interval around the theoretical onset times for Pg or Pn detections, depending on the epicentral distance;
- in the case that a P-type phase could be associated, the detection lists were searched for possible S-type detections in a distance-depending predefined time window;
- relocation of the event with the GERES-observation parameters (phase names, onset times, BAZs) and the applicable GRSN detections;
- in the case of a stable location result, the determined location was distributed automatically to interested addresses in Europe.

A comparison with PDE (USGS) locations indicated that the automatic FEIS-relocation procedure significantly improved the original automatically achieved GERESS location accuracy, in particular for events, which occurred within the GRSN.

#### **9.14.2.3 NORSAR's Event Warning System (NEWS)**

Since 2000, a new quick event-location system was developed at NORSAR to provide fast and reliable solutions in the case of strong events: NORSAR's Event Warning System (NEWS) (Schweitzer, 2003). The whole NEWS algorithm is based on high Signal-to-Noise Ratio (SNR) detections; whenever one of the contributing arrays observes a P-type onset with an SNR larger than a predefined threshold, the NEWS process is initialized.

Once triggered, the NEWS process searches the automatic result lists of all other available arrays for corresponding onsets. Corresponding in this context means that the other onsets have to come from a backazimuth, and with an apparent velocity, which is consistent with the triggering onset. Formulating robust rules for which onsets can eventually be associated with the same event, was a quite cumbersome procedure. However, as implemented today, these rules are built on travel-time differences between the onset times at the different stations, measured backazimuth and apparent velocity of the signals, and SNR of the onsets. In the case of a presumably local or regional event, NEWS also searches for S-type onsets in the onset lists of the arrays.

After all available lists are searched the NEWS process locates the seismic event. To make this automatic event location as robust as possible, onset times and apparent velocity values are only used from first P and S arrivals. However, to use as much as possible information from the seismic arrays, all onsets in compliance with the selection rules and the measured backazimuth values are used to locate the event. Depending on the mean apparent velocity of all detected P onsets, the program defines the event as probably regional, or as near, far or very far teleseismic. Then, together with the mean backazimuth estimation, an initial source region is chosen. Depending on this initial solution, either a regional or a global velocity model is used to locate the event. The observed P amplitudes can be used to calculate a preliminary event magnitude.

For the determination of the source parameters NORSAR's location program HYPOSAT (see PD.11.1) is used. With the limited amount of data available for locating the event, the event's depth cannot be resolved and has therefore to be fixed to a predefined value. However, until now, such preliminary locations have been sufficient for preliminary information to the public in the case of local or regional events. Although the used network of seismic arrays has an aperture of about 18 degrees in the north-south direction, teleseismic events are usually observed over only a very small azimuth range. Therefore, the small number of available observations produces solutions with limited accuracy and large error bars, and some events are even not locatable. This is in particular true for events in the South Pacific, for which only PKP-type onsets can be observed.

On average, NEWS solutions are available between a few and up to about 10 minutes after the first P onsets have been recorded at one of the seismic arrays. A listing of the most recent NEWS solutions is available on the web (<http://www.norsardata.no/NDC/ael/eventmap.html>) and NEWS solutions are disseminated to international data centers, which also work on quick epicenter determinations. The delay of several minutes between the source time and the dissemination of source parameters of regional events by today's NEWS implementation is due to several factors:

- usually, the distance between a seismic event and the closest array recording it is in the order of several hundreds of kilometers;
- it takes several additional minutes until other arrays of the sparse network of arrays in Northern Europe can record the event;
- to achieve a more stable solution for the event location the NEWS algorithm is implemented in such a way that it also waits for possible S-type onsets;
- the location algorithm HYPOSAT (see PD 11.1) used for locating the event may be better optimized for shorter computation time.

### **9.14.3 Usage of seismic arrays to monitor an EEWS relevant site**

With its unique capability to measure not only onset times and amplitudes, but also BAZs and apparent velocities of seismic onsets, an array gives us several possibilities to locate an event. The only question is, which algorithm and data processing scheme should be used to provide quick locations for an EEWS. Working with the above mentioned methods and software packages, one can conclude that with today's computer capacities the most critical parameter for using seismic arrays in an EEWS is the epicentral distance to the array installation(s). All discussed algorithms are on today's computers so fast that the actual calculation times for the different algorithms do not really contribute to EEWS delays. More important are the actual

transmission times of seismic signals since all data connection algorithms work with data frames containing a specific amount of data. The delay time between the actual recording of a signal and its arrival at a data center can vary between seconds and minutes and has to be added to the EEWS times achievable by the discussed location algorithms.

#### **9.14.3.1 The single array case**

In the case of single array locations at local or near regional distances, the travel-time difference between source and arrival time of the first P phase is in the order of tens of seconds for local or near regional events. Additional tens of seconds will be needed to record the first S onset, necessary for calculating the epicentral distance. Therefore, such an array used as an EEWS tool will most likely need more time to locate the event than a traditional seismic network installed in the area of interest. The situation changes in many cases where several seismic active areas or a longer tectonic fault contribute to seismic hazard. Dense, local networks cannot be installed at all places and in particular if more remote or off-shore located zones contribute to a hazard scenario, single array installations can contribute, within a few minutes, with quite reliable event locations for all events within some hundred kilometers epicentral distance. Moreover, as shown by Gibbons et al. (2005), a single array can be tuned for a specific target area and the resulting location precision can become as high as that of a local network, assuming that sufficient calibration information is available. This is of particular interest in case of monitoring the aftershock sequence of a very large earthquake.

In the case of source regions with a higher risk to generate tsunamis, it is of large interest to know quickly not only the hypocenter of the earthquake but also at least a rough estimate of the magnitude and details of the rupture lengths. In such cases, algorithms as proposed and tested by Roessler et al. (2010) could be implemented (see also Section 9.8.6) in a tsunami warning system.

#### **9.14.3.2 A single array and a sparse regional network**

In the case that data from an array and additionally a regional or local network are available, a FEIS-type algorithm can be used. Knowing the BAZ and apparent velocity of the first P-type onset directly gives information about the direction in which the event occurred and if it was at a local or a regional distance. For regional events, the first P onset should have an apparent velocity typical for Pn phases and for local events typical for Pg onsets, respectively. With this information, the array result for the first P onset directly indicates, which single station records should be added to achieve a fast and more reliable event location.

An EEWS based on a single array and a sparse network can provide a first, quick and reasonably good event location at local or near regional distance ( $D < 400$  km) within the first minutes after the event origin time (OT) as long as one of the network stations is located as close as the array or closer to the event.

#### **9.14.3.3 Multiple array configuration**

In the case of observations from two or more arrays, a GBF- (see Section 9.13.5) or NEWS-type algorithm can be implemented. Recording one onset from each array with a BAZ

estimate is already sufficient to locate the source area. If the target fault zone is located between two arrays, which have a distance of about 200 km from each other, such an installation is sufficient to locate the main shock and the whole aftershock sequence on the fault zone within about 30 seconds after OT. Events, which are not located between the two arrays, will be located within 20 s plus the absolute travel time of the first P onset to one of the arrays.

This scenario of course assumes that the data of the two arrays are available in real time for fully automated array processing software. The location capabilities and precision will in general increase with a larger number of arrays. In such cases, different arrays may be also combined to monitor simultaneously different target areas.

## Acknowledgments

The authors thank John B. Young (Blacknest) for reprints of publications from the old days of array seismology in Great Britain, and Peter Bormann, Brian Kennett, Frank Scherbaum, and Lyla Taylor for critical reviews of the manuscript of this chapter in the first NMSOP edition of 2002. We thank Hanneke Paulssen, John Coyne and Peter Bormann for critically reviewing the new 2011 version of this chapter and for many helpful comments on how to improve it. Main parts of Section 9.14 were compiled during NORSAR's participation in the SAFER project, funded under the Sixth Framework Programme of the European Commission (Project Number 036935).

### 10.1 Introduction

Seismology entirely depends on co-operation, both national and international cooperation. Only the accumulation of large sets of compatible high quality data in standardized formats from many stations and networks around the globe and over long periods of time will yield sufficiently reliable long-term results in event localization, seismicity rate and hazard

assessment, investigations into the structure and rheology of the Earth interior and other priority tasks in seismological research and applications.

For almost a century, only parameter readings taken from seismograms were exchanged with other stations and regularly transferred to national or international data centers for further processing. Because of the uniqueness of traditional paper seismograms and lacking opportunities for producing high-quality copies at low cost, original analog waveform data, cumbersome to handle and prone to damage or even loss, were rarely exchanged. The procedures for carefully processing, handling, annotating and storing such records have been extensively described in the 1979 edition of the *Manual of Seismological Observatory Practice* (Willmore, 1979) in the chapter *Station operation*. They are not repeated here. Also the traditional way of reporting parameter readings from seismograms to international data centers such as the U.S. Geological Survey National Earthquake Information Center (NEIC), the International Seismological Centre (ISC) or the European Mediterranean Seismological Centre (EMSC) are outlined in the old manual in detail in the section *Reporting output*. They have not changed essentially since then, although methods to exchange parameter data did change dramatically. On the other hand, respective working groups on parameter formats of the IASPEI and of its regional European Seismological Commission (ESC) have meanwhile debated for many years, how to make these formats more homogeneous, consistent and flexible so as to better accommodate also other seismologically relevant parameter information.

Any data report must, of course, follow a format known to the recipient in order to be successfully parsed. Some of the goals for any format are:

- *concise*                avoiding unnecessary expense in transmission and storage
- *complete*            providing all of the information required to use the data
- *transparent*        easily read by a person, perhaps without documentation
- *simple*                straightforward to write and parse with computer programs

Traditional formats for reporting parameter data sacrificed simplicity, transparency and even sometimes completeness in favor of the other goals. With the falling cost of data storage and exchange, modern formats more often sacrifice conciseness in favor of transparency and simplicity.

Modern parameter formats, in addition, are usually extensible and include “metadata”. An extensible format includes some way for new types of data to be introduced without either collecting all of the new information into unformatted comment strings or making messages with the new data types unreadable by old parsers. “Metadata” are information about the data, such as how and by whom the data were prepared. For waveform data the term metadata includes all information on the station and sensor/data acquisition system that produces the data.

The Telegraphic Format (TF), as documented in the *Manual of Seismic Observatory Practice* (Willmore, 1979) is an extreme example of a traditional format for reporting and exchanging parameter data. Since telex was very expensive compared with the modern communication costs, conciseness was the paramount goal even to the point of occasional ambiguity. The year of the data, for example, might be excluded if the recipient could probably infer it. The format was intended for use in an era when many stations were isolated and could report little more than their own phase readings, so event parameters such as hypocenter and magnitude are relegated to a secondary role. The TF incorporated further restrictions due to the special

limitations of telex messages, such as no lower-case letters and sometimes no control over line breaks.

A seismic network with modern, calibrated instruments can provide far more information than telegraphic format allows, while low-cost e-mail has eliminated the restrictions and high costs of telex messages. Consequently, since at least 1990 most seismic parameter data have been stored and exchanged in modern formats that are more complete, simpler and usually more transparent than the Telegraphic Format. But until recently there was no generally accepted standard modern format. A major step forward in this direction was made by the Group of Scientific Experts (GSE) organized by the United Nations Conference on Disarmament. It developed GSE/IMS formats (see 10.2.4) for exchanging parametric seismological data in tests of monitoring the Comprehensive Test Ban Treaty (CTBT) (see 10.2.4) which became popular also with other user groups. Seismological research, however, has a broader scope than the International Monitoring System (IMS) for the CTBT. Therefore, a new *IASPEI Seismic Format* (ISF), compatible with the IMS format but with essential extensions, has been developed and adopted by the Commission on Seismological Observation and Interpretation of the International Association of Seismology and Physics of the Earth's Interior at its meeting in Hanoi, August 2001. It is the conclusion of a 16-year process seeking consensus on a new format and fully exploits the much greater flexibility and potential of E-mail and Internet information exchange as compared to the older telegraphic reports (see 10.2.5). Since 2001 new developments have been introduced due to technology changes. The introduction of XML resulted in the requirement of a standard schema for the representation of parameter data: QuakeML (<https://quake.ethz.ch/quakeml/QuakeML>). QuakeML is a collaborative effort, which started within the NERIES project, and presents an open standard.

Digital waveform data, however, are nowadays by far the largest volume of seismic data stored and exchanged world-wide. The number of formats in existence and their complexity far exceeds the variability for parameter data. With the wide availability of continuous digital waveform data and unique communication technologies for world-wide transfer of such complete original data, their reliable exchange and archival has gained tremendous importance. Several standards for exchange and archival have been proposed, yet a much larger number of formats are in daily use. The purpose of the section on digital waveform data is to describe the international standards and to summarize the most often used formats. In addition, there will be a description of some of the more common conversion programs.

Due to the rapid increase of seismological stations, the practice of an international registry of station names (ISC, NEIC) became difficult to maintain. New definitions of station codes have been discussed within IASPEI and FDSN since 2005 and approved by IASPEI and its Commission on Seismic Observation and Interpretation (CoSOI) at the 2009 Cape Town General Assembly (see IS 10.3).

However, beforehand, a short description of the most common parameter formats will be given in the following section.

## 10.2 Parameter formats

Parameter formats deal with all earthquake parameters like origin times, hypocenter coordinates (longitude, latitude and depth), phase names and phase arrival times, maximum amplitudes and periods of different seismic phases or wave groups as recorded by different

types of seismographs, magnitudes calculated from such amplitude and period readings, etc. Until recently, there were no real standards, except the Telegraphic Format (TF) used for many years to report phase arrival, amplitude and period data to international agencies (Willmore, 1979; chapter “Reporting output”). The format is not used for processing. There have been attempts to modernize TF for many years through the IASPEI Commission of Practice (now the Commission on Seismological Observation and Interpretation) and as mentioned in the introduction, the IASPEI Seismic Format (ISF) was approved as a standard in 2001 (see section 10.2.5). Recently IASPEI (2005 and 2011) has adopted measurement standards for several widely used magnitudes. The standard nomenclature for reporting such magnitudes and related amplitude and period data in accordance with the ISF format have been outlined in IS 3.3 as well as in Chapter 3, sections 3.2.7.3 and 3.2.7.5. An example is given in Tab. 10.5 below. In practice, however, still many different formats are used and the most dominant ones have come from popular processing systems. In the following, some of the most well known formats will be briefly described. For complete description of the formats, the reader is referred to original manuals or publications.

### 10.2.1 HYPO71

The very popular location program HYPO71 (Lee and Lahr, 1975) has been around for many years and has been the most used program for local earthquakes. The format was therefore limited to work with only a few of the important parameters. Tab. 10.1 gives an example.

**Tab. 10.1** Example of an input file in HYPO71 format. Each line contains, from left to right: Station code (max 4 characters), E (emergent) or I (impulsive) for onset clarity, polarity (C – compression; D – dilatation), year, month, day, and time (hours, minutes, seconds, hundredth of seconds) for P-Phase, second for S-phase (seconds and hundredth of seconds only), S-phase onset and, in the last column, duration. The blank space between ES and duration has been used for different purposes like amplitude. The last line is a separator line between events and contains control information.

|         |                 |         |     |
|---------|-----------------|---------|-----|
| FOO EPC | 96 6 6 64848.47 | 62.67ES | 136 |
| MOL EPC | 96 6 6 64849.97 | 65.87ES | 144 |
| HYA EP  | 96 6 6 64856.78 | 78.07ES | 135 |
| ASK EP  | 96 6 6 649 2.94 | 34.72ES | 183 |
| BER EPC | 96 6 6 649 7.56 | 36.61ES |     |
| EGD EPD | 96 6 6 649 5.76 | 40.53ES |     |
|         | 10 5.0          |         |     |

The format is rather limited since only P or S phase names can be used and the S-phase is referenced to the same hour-minute as the P-phase and the format cannot be used with teleseismic data. However, the format is probably one of the most popular formats ever for local earthquakes. The HYPO71 program has seen many modifications and the format exists in many forms with small changes.

### 10.2.2 HYPOINVERSE

Following the popularity of HYPO71, several other popular location programs followed like Hypoinverse (Klein, 1978) and Hypoellipse (Lahr, 1989). Tab. 10.2 gives an example of the input format for Hypoinverse.

**Tab. 10. 2** Example of the Hypoinverse input format. Note that year, month, day, hour, min is only given in the header and only one phase is given per line.

### 10.2.3 Nordic format

In the 1980's, this was one of the first attempts to create a more complete format for data exchange and processing. The initiative came from the need to exchange and store data in Nordic countries and the so-called Nordic format was agreed upon among the 5 Nordic countries. The format later became the standard format used in the SEISAN data base and processing system and is now widely used. The format tried to address some of the shortcomings in HYPO71 format by being able to store nearly all parameters used, having space for extensions and useful for both input and output. An example is given in Tab. 10.3.

**Tab. 10. 3** Example of Nordic format. The data is the same as seen in Tabs. 10.1 and 10.2. The format starts with a series of header lines with type of line indicated in the last column (80) and the phase lines are following the header lines with no line type indicator. There can be any number of header lines including comment lines. The first line gives among other things, origin time, location and magnitudes, the second line is the error estimate, the third line is the name of the corresponding waveform file and the fourth line is the explanation line for the phases (type 7). The abbreviations are: STAT: Station code, SP: component, I: I or E, PHAS. Phase, W: Weight, D: polarity, HRMM SECON: time, CODA: Duration, AMPLIT: Amplitude, PERI: Period, AZIMU: Azimuth at station, VELO: Apparent velocity, SNR: Signal-to-noise ratio, AR: Azimuth residual of location, TRES: Travel time residual, W: Weight in location, DIS: Epicentral distance in km and CAZ: Azimuth from event to station.

## 10.2.4 The GSE/IMS formats

Also in the late eighties, a new format was created for exchange of data within the International Monitoring System (IMS) of the Comprehensive Test Ban Treaty Organization (CTBTO), formally called the GSE (Group of Scientific Experts) parameter format. The format used in the GSE's Technical Test 3 (GSETT-3) was designated GSE2.0 and came to be used even by seismologists uninvolved in CTBT monitoring.

Following GSETT-3, a significantly revised format was originally designated GSE2.1, but renamed IMS1.0 when it was adopted for use by the International Data Center planned to monitor the CTBT when it enters into force. The format IMS1.0 is similar in structure to the Nordic format, however more complete in some respects and lacking features in other respects. A major difference is that the line length can be more than 80 characters long, which is not the case for any of the previously described formats. After SEISAN, it is the first major format for which completeness or readability was recognized as a more important design goal than conciseness. The IMS1.0 format is available from the ISC web site via <http://www.isc.ac.uk/standards/isf> and [ftp://ftp.isc.ac.uk/pub/isf/isf\\_ext.pdf](ftp://ftp.isc.ac.uk/pub/isf/isf_ext.pdf). IMS1.0 has been used extensively for data exchange within the institutions participating in the IMS and also been used for data exchange outside IMS like in the popular AutoDRM system ([http://www.seismo.ethz.ch/prod/autodrm/index\\_EN](http://www.seismo.ethz.ch/prod/autodrm/index_EN)) and for transmission to international centers. However, IMS has been used less as a processing format than HYPO71 and Nordic formats.

**Tab. 10.4** An example of the IMS1.0 parameter format. The example contains the same data as given in Tabs. 10.1 to 10.3. The first lines are message information etc. The remaining lines are more or less self-explanatory. Note that more information, with a higher accuracy, can be given for each phase (like magnitude) than in the Nordic format. On the other hand, information like component and event duration is missing. These are added in the new ISF format.

## 10.2.5 The IASPEI Seismic Format (ISF)

The need for a common and widely accepted parameter format for comprehensive seismological data exchange has led to the IASPEI Seismic Format (ISF), adopted as standard in August 2001. ISF conforms to the IMS1.0 standard but has essential extensions for reporting additional types of data. This allows the contributor to include complementary data considered to be important for seismological research and applications by the IASPEI Commission on Seismological Observation and Interpretation. The format looks almost like the IMS1.0 example in Tab. 10.4 above, except for the extensions. The ISF has been comprehensively tested at the ISC and NEIC and incompatibilities have been eliminated. The detailed description of the ISF is available from the ISC home page and kept up-to-date there (see [ftp://ftp.isc.ac.uk/pub/isf/isf\\_ext.pdf](ftp://ftp.isc.ac.uk/pub/isf/isf_ext.pdf)). It is not reproduced in this manual.

Consensus on the ISF was reached partly by including many optional items, so the format is not as simple as some alternatives. Despite this, the completeness, transparency, extensibility and metadata of ISF are expected to make it very widely used. Wide use of ISF will bring back the advantages of a generally accepted standard so that it becomes easier to exchange data, re-use data collected for past projects, and employ programs developed elsewhere.

In the Information Sheets IS 10.1 and IS 10.2, examples are given how event parameter data and unassociated parameter readings by seismic stations are reported according to the IMS format with ISF extensions.

Tab. 10.5 below gives an abridged example of an USGS/NEIC Hydra System data printout in the IMS1.0 format of calculated event parameters and station parameter readings. Yet, for brevity, several columns in the original listing have been left out in order to highlight the new, more differentiated way of magnitude, amplitude and period reporting. It helps to recognize easily which amplitudes and magnitudes have been measured according to the IASPEI (2005) recommended standards and which ones not, whether the amplitudes are displacement or velocity amplitudes and at what “amplitude phase” time these parameters have been “picked”. This assures later on an unambiguous reproduction or check of these parameter determinations.

**Tab. 10.5** Cut-out of an event and station parameter plot in IMS1.0/ISF parameter format produced by the USGS/NEIC HYDRA automatic location and analysis system. Note the IASPEI (2005) standard magnitudes mb, mb\_Lg, mB\_BB, Ms\_BB and Ms\_20. BB stands for unfiltered velocity broadband records, 20 for surface waves with periods of 20±2 s measured in WWSSN-LP filtered records. In contrast, mb and mb\_Lg are measured on WWSS-SP filtered records. Letters preceding the magnitude symbol in the “amplitude-phase name” column stand for: I - IASPEI standard, A - displacement amplitude in nm and V - velocity amplitude in nm/s. The next column gives the time at which the respective amplitudes and periods have been measured. Additionally, NEIC also determines several non-standard magnitudes.

## 10.3 Digital waveform data

Many different formats for digital data are used today in seismology. For a summary and the abbreviations used, see the following sections. Most formats can be grouped into one of the following five classes:

1. Local formats in use at individual stations, networks or used by a particular seismic recorder (e.g., ESSTF, PDR-2, BDSN, GDSN; mini-SEED).
2. Formats used in standard analysis software (e.g., SEISAN, SAC, AH, BDSN; mini-SEED).
3. Formats designed for data exchange and archiving (SEED, GSE).

4. Formats designed for database systems (CSS, SUDS).
5. Formats for real time data transmission (IDC/IMS, Earthworm; mini-SEED).

Use of the term "designed" in describing Class 3 and 4 formats is intentional. It is usually only at this level that very much thought has been given to the subtleties of format structure which result in efficiency, flexibility, and extensibility.

The four classes (1-4) show a hierarchical structure. Class 4 forms a superset of the others, meaning that classes 1-3 can be deduced from it. The same argument applies to class 3 with respect to classes 1 and 2. Nearly all format conversions performed at seismological data centers are done to move upwards in the hierarchy for the purpose of data archiving and exchange with other data centers. Software tools are widely available to convert from one format to another and particularly upwards in the hierarchy.

This hierarchy also explains why there are so many formats. The design of class 1 formats depends on the manufacturer of the data acquisition system. In the early days of digital seismometry, display and analysis software was often proprietary and marketed specifically for a certain manufacturer's equipment and data format. There was no real need for manufacturers to adhere to a standard recording format, until users began to realize the advantages of exchanging data with other seismologists and discovered that this was quite difficult unless the other party was using the same hardware and/or software.

Station operators who were not satisfied with the proprietary analysis software supplied with the procured data acquisition systems started to convert data from Class 1 formats into the Class 2 formats which were used by more powerful and widely available analysis packages such as SAC. These programs usually provide subroutines that make conversion from local formats fairly easy. Analysis packages (e.g., SeisGram) which are developed around a Class 1 format (BDSN in this case) implicitly offer their format preference as a candidate for a new standard in Class 2, but it hardly matters as long as the necessary software tools are available to convert to and from the data exchange formats.

The GDSN (Global Digital Seismic Network) format began as a Class 1 format, but because it was used by an important global seismograph network (DWWSSN, SRO) it became accepted as a de facto standard for data exchange (Class 3). The beginning of widespread international data exchange within the FDSN (Federation of Digital Seismic networks) and GSE (Group of Scientific Experts) groups in the late 1980's revealed the GDSN format's weaknesses in this role and put in motion the process of defining more capable exchange formats.

The volume of commonly available digital seismic data continues to increase dramatically. It increased from 600 MB annually in 1980 to 300 GB in 1992 and today we are talking about many terabytes. Database systems, which are specially designed to handle these large datasets, have therefore begun to appear as a superset of the standard data exchange formats. The SUDS system was an example of this type of format, however today it is little used.

In the 1990's, several activities (e.g., the GSETT-3 experiment and the U.S. National Seismograph Network (USNSN)) emerged featuring real-time exchange of seismological data, and interest focused on formats which are suitable for such applications. In the late 1990's, this idea was carried farther by systems such as Earthworm, which implemented format-independent protocols. Earthworm also is designed to exchange data across a peer

network of multiple, independent nodes, as well as in a traditional network of dependent nodes with a centralized collection and distribution center.

Following is a brief description of some of the classes of formats as defined above.

### 10.3.1 Data archival

Data archival requires the storage of complete information on station, channel(s) and the structure of the data. Most existing formats are designed to provide part of the information. Most archival formats presently in use do include info on station and channel, but are not always complete in the description of the data. What we envisage is demonstrated through several features in the Standard for the Exchange of Earthquake Data (SEED) format:

- Data Description Language (DDL)
- Reference to byte order
- Response information

The DDL is defined to enable the data itself to be stored in any data format (integer, binary, compressed). The language consists of a number of keys defining, for example, the applied compression scheme, number of bytes per sample, mantissa and gain length in bits and the use of the sign convention. The reader interprets the DDL and knows exactly how to deal with the data. The advantage of the DDL is that the original data structure can be maintained and is known. A disadvantage is that readers will have to interpret the DDL and have less performance in reading. However, the decoding information is available directly with the data and this is extremely important, since data are collected on platforms having different byte orders. In SEED the byte order of the original data is defined in the header, so the reader will be able to decide whether bytes should be swapped.

In most archival formats, response information can be supplied in terms of poles and zeroes. Fewer efforts are undertaken to give the FIR filter coefficients in the header, although they are accounted for in the definition of SEED and GSE2.X. A problem occurs when a description of the instrument response is given only in measured amplitude and phase data as a function of frequency, as is the case in the GSE1.0 format. Also, the GSE2.X does not specify the minimum requirement. The main purpose of the response information is to correct for instrument response and thus the user will have to find the best fitting poles and zeroes to the given response. Although tools are available to calculate poles and zeroes from frequency, amplitude and phase data (e.g., in Preproc), results from the multiple inversion of the discrete frequency, amplitude and phase data will be different from the original data.

The deployment of large mobile arrays consisting of heterogeneous instrumentation is an important research tool. Data archival of these data is important. Although there is a tendency to store the data in a common format, the responses of sensors and data acquisition systems are often poorly known. It is recommended to pay attention to this issue before the experiment starts!

Finally, an issue in data archival is the responsibility of the data quality and the mechanism of reporting data errors. The network/station operator is responsible for the quality of the original data. However, the data may be subjected to format conversion at a remote data center. This last stage could introduce errors and it is the originator of the data, which must be

responsible for data quality and should agree on the final conversion, if such a conversion is done externally.

### 10.3.2 Data exchange formats

The data exchange formats are closely related to the way data is exchanged. Therefore, these formats are described separately in this section. Essentially, any format can be used for exchange, however the idea of an exchange format is to make it easy to send it electronically, to have a minimum standard of content and be readable on all computer platforms. Today, the de-facto standard within the FDSN is the mini-SEED or SEED format ([http://www.iris.edu/manuals/SEED\\_chpt1.htm](http://www.iris.edu/manuals/SEED_chpt1.htm)).

At present, there are many different techniques in use to exchange data, either between data users and data centers or between data centers. Since the beginning of the 21<sup>st</sup> century techniques to transmit and exchange data in real-time became very popular and efficient, and the volume of continuous waveform data has grown very fast. With this rapid increase of continuous data, maintenance and adaptation of existing techniques and development of new techniques for requesting selected datasets only. Nowadays, the most common format which is used in real-time and request mechanisms for data exchange is (mini-)SEED. An overview of existing data request techniques is given below.

|                         | Technique                                                                      | Advantage                                     | Disadvantage                            |
|-------------------------|--------------------------------------------------------------------------------|-----------------------------------------------|-----------------------------------------|
| <b>Indirect on-line</b> | autoDRM, NetDC, breq-fast                                                      | email based<br>(no connection time)           | small volume or<br>download through ftp |
| <b>Direct on-line</b>   | ftp, WWW, DRM<br>(Wilber/FARM); DHI,<br>ArcLink, webservices,<br>QuakeExplorer | direct access, enables<br>easy data selection | slow for large data<br>volumes          |
| <b>Off-line</b>         | CD-ROM (DVD)                                                                   | direct access                                 | no real-time data                       |

Indirect on-line data exchange is arranged through (automated) *Data Request Managers* (DRMs) where the request mechanism is based on email traffic. One of the earliest systems was AutoDRM (<http://seismo.ethz.ch/autodrm>), a standardized protocol using the GSE defined syntax. One step further is the implementation of a communication protocol for exchange between data centers in such a way that a user only has to send one request to a nearby data center node. His/her request is then automatically routed through the data centers that may contribute to the requested data set. Such a protocol is the NetDC system (Casey and Ahern, 1996). A similar system, called ArcLink, was developed by GFZ (GEOFON) using a more simple communication protocol over a TCP/IP socket, making it a direct on-line request mechanism

One basic problem in using email as the transport mechanism is the restricted data volume that can be exchanged. Also, the format sometimes will have to be ASCII. The format issue is taken care of in the GSE format, although in the description of the AutoDRM protocol it is mentioned that also a format like SEED can be used. The only difference is that the user is requested to get the data through anonymous ftp (pull) or the data is pushed into an anonymous ftp area defined by the user. The AutoDRM system at the Orfeus Data Centre

(ODC) supports both the SEED and GSE format in data exchange. Both NetDC and ArcLink provide mini-SEED waveform data.

*Direct on-line access to data* is arranged at the ODC (<http://www.orfeus-eu.org/>) for example through ftp, a web-interface and web services. Web services provide machine-accessible data services typically accessed through the standard HTTP protocol. In many cases these services are publicly exposed so that users may access them directly through their own applications. Other data centers, like IRIS-DMC and GEOFON, have similar web-based techniques. An example of an application using web services is the NERIES portal (<http://www.neries-eu.org>) through which a user can search for earthquake data in the EMSC database and download waveform data through the ODC.

Internet speed presently may still be limiting the usefulness of this direct on-line data exchange, especially since the volumes that are to be transferred may be huge. One major advantage of direct on-line availability of the data is the capability to make a selection out of the vast amount of digital data. Procedures are presently under development to increase the power of these selection tools, for example through the above mentioned portal and webservices developments.

*Off-line data access* provides complete, quality controlled data that are locally available at each institute in the form of CD-ROMs or DVD's. The completeness and quality control takes time and CD-ROMs and DVD's have a limited storage capacity.

### **10.3.3 Formats for data base systems**

Formats for data base systems are specially designed and no details will be given here. Examples of such formats are CSS and the derived "IDC Database Schema" (see Information Sheet IS 10.3) and SUDS.

### **10.3.4 Continuous data protocols and formats**

With better communication systems, real time transmission of digital data has become common. There is no internationally agreed upon protocol for this and equipment manufacturers often use their own formats. However, the number of protocols is limited, and the most common systems are SeedLink, SCREAM, NAQS, CD1.x, Antelope, EarthWorm, NRTS and LISS. A number of open-source and commercial data exchange systems exist between the different systems, and may be included in the protocol software or may be found on the appropriate web sites. Complete documentation for the CD-1.0 protocol used for the transmission of IMS data as described under 10.2.4. is now being replaced by the CD-1.1 protocol. Descriptions for both can be found on the secure web site <https://www2.ctbto.org> (authorized users only) and openly on <http://www.geoinstr.com/pub/manuals/343r02p.pdf>.

At present, a large number of channels from a station or array of stations can be transmitted in near-real time using a single connection. Digital data are provided in compressed or uncompressed format and with or without authentication signatures. The protocol uses units of information called frames to establish or alter a connection and to exchange data between

the sender and the receiver. Only one frame is being transmitted or received at any instance. A time-out is used in case of lost connection.

*Establishing connections.* The sender initiates the connection with the receiver to a pre designated IP address and port by sending a Connection Request Frame. The receiver validates the authenticity of the sender and provides a new port and Internet Protocol (IP) address in a Port Assignment Frame. The sender drops the original connection and connects to the assigned IP address and port that is subsequently used for all data transfer.

*Transmitting data.* After the connection is established, the sender sends a Data Format Frame, which describes the format of the subsequent Data Frames. The sender can then send Data Frames data. The Data Format Frame provides information about itself and about Data Frames that will follow. The Data Frame contains the raw time series data. Each Data Frame has a single Data Frame Header and multiple channel sub-frames.

*Altering connections.* Either sender or the receiver can alter the connection through the exchange of Alert Frames. The receiver sends the Alert Frame to notify the sender to use a different port. The sender uses Alert Frames to notify the receiver that the communication will cease or that a new data format is about to be used.

*Terminating connections.* Typically, an established connection remains active and in use until the sender or receiver terminates it for maintenance or reconfiguration. The connection can be intentionally terminated by sending an Alert Frame. Unintentional termination due to a slow or failed communications system is detected after the time-out period.

Documentation for the Earthworm protocol can be found on the USGS website <http://folkworm.ceri.memphis.edu/ew-doc/> .

## 10.4 Some commonly encountered digital data formats

This section gives an alphabetical list of common formats in use by several recording or analysis programs. For each format some description is given. For several more specific, proprietary, now outdated or rarely used and platform formats we refer to Chapter 10, pages 12-16, in the first edition of NMSOP (DOI: 10.2312/GFZ.NMSOP\_r1\_ch10; <http://nmsop.gfz-potsdam.de> and <http://www.isc.ac.uk/standards> ).

### AH

Class: 2

The Ad Hoc (AH) format is used in the AH waveform analysis software package developed at Lamont Doherty Geological Observatory, New York, USA. This package also supports a number of conversion tools.

### CSS

Class: 2,4

The Center for Seismic Studies (CSS) Database Management System (DBMS) was designed to facilitate storage and retrieval of seismic data for seismic monitoring of test ban treaties [CSS]. The seismic data separate into two categories: Waveform data and parametric data.

For the parameter data, the design utilizes a commercial relational database management system. Information is stored in relations that resemble flat, two-dimensional tables as in the ISF format (see Information Sheet IS 10.1). The description of waveform data is physically separated from the waveform data itself. The index to the waveform archive is maintained within the relational database. Data are stored in plain files, called non-DBMS files. Each non-DBMS file is indexed by a relation that contains information describing the data and the physical location of the data in the file system. Each waveform segment contains digital samples from only one station and one channel. The time of the first sample, the number of samples and the sample rate of the segment are noted in an index record. The index also defines in which file and where in the file the segment begins, and it identifies the station and channel names. A calibration value at a specified frequency is noted. The index records are maintained in the **wfdisc** relation. Each **wfdisc** record describes a specific waveform segment and contains an id number to designate detailed information on the station and instrumentation of the trace.

## **GSE**

### Class 3

The format proposed by the Group of Scientific Experts (GSE format) has been extensively used with the GSETT projects on disarmament. The GSE2.1, now renamed IMS1.0, is the most recent version. The manual can be downloaded from [http://www.seismo.ethz.ch/prod/autodrm/manual/provisional\\_GSE2.1.pdf](http://www.seismo.ethz.ch/prod/autodrm/manual/provisional_GSE2.1.pdf).

A GSE2.1 waveform data file consists of a waveform identification line (WID2) followed by the station line (STA2), the waveform information itself (DAT2), and a checksum of the data (CHK2) for each DAT2 section (Provisional GSE 2.1 Message Formats & Protocols, 1997). The default line length is 132 bytes. No line may be longer than 1024 bytes. The response data type allows the complete response to be given as a series of response groups than can be cascaded. Response description is made up of the CAL2 identification line plus one or more of the PAZ2, FAP2, GEN2, DIG2 and FIR2 response sections in any order.

Waveform identification line WID2 gives the date and time of the first data sample; the station, channel and auxiliary codes; the sub-format of the data, the number of samples and sample rate; the calibration of the instrument represented as the number of nanometers per digital count at the calibration period; the type of the instrument, and the horizontal and vertical orientation.

Line STA2 contains the network identifier, latitude and longitude of the station, reference coordinate system, elevation and emplacement depth.

Data section after DAT2 may be in any of six different sub-formats recognized in the GSE2.1 waveform format: INT, CM6, CM8, AUT, AU6, and AU8. INT is a simple ASCII sub-format, "CM" sub-formats are for compressed data and "AU" sub-formats are for authentication data. All represent the numbers as integers and therefore can be sent by email.

A checksum CHK2 must be provided in the GSE2.1 format. The checksum is computed from integer data values prior to converting them to any of the sub-formats.

## **SAC**

Class 2

Seismic Analysis Code (SAC) is a general-purpose interactive program designed for the study of time sequential signals [SAC]. Emphasis has been placed on analysis tools used by research seismologists. A SAC data file contains a single data component recorded at a single seismic station. Each data file also contains a header record that describes the contents of that file. Certain header entries must be present (e.g., the number of data points, the file type, etc.). Others are always present for certain file types (e.g., sampling interval, start time, etc. for evenly spaced time series). Other header variables are simply informational and are not used directly by the program. Although the SAC analysis software only runs on Unix platforms and the general format is binary, there is also an ASCII version that can be used on any platform.

## **SUDS**

Class: 1,2,4 Platform: PC

SUDS stands for “The Seismic Unified Data System”. The SUDS format was launched to be a more well thought out format useful for both recording and analysis and independent of any particular equipment manufacturer. The format has seen widespread use, but has lost some momentum, partly because it is not made platform independent.

## **10.5 Format conversions**

### **10.5.1 Why convert?**

Ideally, we should all use the same format. Unfortunately, as the previous descriptions have shown, there are a large number of formats in use. With respect to parameter formats, one can get a long way with HYPO71, Nordic and GSE/ISF formats for which converters are available, such as in the SEISAN system. For waveform formats, the situation is more complicated. First of all, there are many different formats, and, since most are binary, there is the added complication that some will work on some computer platforms and not on others. This is particularly a problem with binary files containing real numbers as for example, the SeisGram format. Additional problems are: Some formats have seen slight changes and exist in different versions, different formats have different contents so not all parameters can be transferred from one format to another and conversion programs might not be fully tested for different combinations of data.

Many processing systems require a higher level format than the often primitive recording formats so that is probably the most common reason for conversion, and a similar reason is to move from one processing system to another.

The SEED format has become a success for archival and data exchange. Initially, it was not very useful for processing purposes, however now it is more widely used also for processing. Sometimes it is important to be able to move down in the hierarchy to be able to use a particular processing system. Thus, the main reasons for format conversion can be summarized as:

- Moving upwards in the hierarchy of formats for the purpose of data archiving and exchange

- Moving downward from the archive and exchange formats for analysis purposes
- Moving across the hierarchy for analysis purposes
- Moving from one computer platform to another

### 10.5.2 Ways to convert

There are essentially two ways of converting. The first is to request data from a data center in a particular format or to log into a data center and use one of their conversion programs. The other more common way is to use a conversion program on the local computer. Such conversion programs are available both as free standing software and as part of processing systems. Equipment manufactures will often supply at least a program to convert recorder data to some ASCII format and very often also to the more standard format MiniSeed.

### 10.5.3 Conversion programs

Since conversion programs are often related to analysis programs, we list in Tab. 10.6 some of the better-known analysis systems and the format they use directly.

**Tab.10.6** Examples of popular analysis programs.

| Program        | Author(s)                           | Input format(s)                  | Output format(s) |
|----------------|-------------------------------------|----------------------------------|------------------|
| Geotool        | J.Coyne                             | CSS, SAC, GSE                    | CSS, SAC, GSE    |
| SAC            | IRIS                                | SAC                              | SAC              |
| SEISAN         | J.Havskov, L. Ottemöller,<br>P.Voss | SEISAN, GSE                      | SEISAN, GSE, SAC |
| SeismicHandler | K.Stammler                          | miniSEED, GSE, AH, ESSTF,<br>GCF | GSE, miniSEED    |
| SNAP           | M.Baer                              | SED, GSE                         | SED, GSE         |

An overview of available format conversion programs can be found on the ORFEUS Web pages under ORFEUS Seismological Software Library (<http://orfeus.knmi.nl/wirjung.groups/wg4/index.html>). Here we present just a few packages in alphabetical order. Only those programs are mentioned which are able to read at least one of the formats mentioned in sub-chapter 10.4.

#### Codeco

Program **codeco** was written by U. Kradolfer and modified by K. Stammler and K. Koch. Input files can be in SAC binary or ASCII, or GSE formats. Output formats are: integer or compressed GSE1.0 or GSE2.0, SAC binary or ASCII, and miniSEED. **Codeco** is available through the SZGRF software library (<ftp://ftp.szgrf.bgr.de/pub/software> ).

## GSE to SEED

Program **gse2seed**, developed by R. Sleeman (Orfeus Data Centre, de Bilt), converts a GSE2.X file to the SEED2.3 format. Multiple traces are handled. For each WID2 section, the GSE file must contain corresponding data types STATION, CHANNEL and RESPONSE. This program was originally developed to convert both metadata and waveform data, but is maintained nowadays only to convert GSE metadata into dataless SEED. Conversion of GSE waveform data into mini-SEED can be done by **gse2mseed**, developed by Chad Trabant (IRIS DMC).

## PASSCAL package

The PASSCAL package was written by P. Friberg, S. Hellman, and J. Webber, developed on SUN under SunOs4.1.4, compiled under Solaris 2.4 and higher and also under LINUX. It converts RefTek to SEG Y and miniSEED. Program **pql** provides a quick and easy way to view SEG Y, SAC, miniSEED or AH seismic data. **pql** operates in the X11 window environment. The package is available from the PASSCAL instrument center (<http://www.passcal.nmt.edu>) at New Mexico Tech., Socorro.

## Preproc

**Preproc** has been designed to assist the seismologist who wishes to analyze large sets of raw digital data that need to be preprocessed in some standard way prior to the analysis. Preproc was written by Miroslav Zmeskal for the ISOP project in the period 1991-1993. It was rewritten recently in the object-oriented form. As a by-product, **preproc** can perform data conversion from GSE / PITSA ISAM to GSE / PITSA ISAM. In the near future new input/output formats will be implemented (ESSTF, miniSEED). **preproc** was successfully compiled on HP, SUN, Linux and DOS. Program package **preproc** and a detailed manual are available through the ORFEUS Seismological Software Library

## Rdseed

**Rdseed** reads from the input tape or file in the SEED format. According to the command line function option specified by the user, **rdseed** will read the volume and recover the volume table of contents ( -c), the set of abbreviation dictionaries ( -a), or station and channel information and instrument response table ( -s). In order to extract data from the SEED volume for analysis by other packages, the user must run **rdseed** in user prompt mode (without any command line options). As data is extracted from the SEED volume, **rdseed** looks at the orientation and sensitivity of each channel and corrects the header information on request. Implemented output formats are (option d): SAC, AH, CSS 3.0, miniSEED and SEED. A Java version of rdseed is to be released in 2001. **Rdseed** was developed by Dennis O'Neill and Allen Nance, IRIS DMC.

**SeedStuff** is a set of basic programs provided by the GEOFON DMS software library in Potsdam (<ftp://ftp.gfz-potsdam.de/pub/home/st/GEOFON/software>) to process and compile raw data from Quanterra, Comserv and RefTek data loggers. The goal is to check and extract

data from station files/tapes to miniSEED files and to assemble miniSEED files to full SEED volumes. The SeedStuff package was written by Winfried Hanka and compiled on the SUN, HP and Linux. The following tools are available:

extr\_qic: extracts multiplexed raw Quanterra station tapes to demultiplexed miniSEED files containing only one station / stream / component  
extr\_file: like extr\_qic for multiplexed miniSEED, RefTec files  
extr\_fseed: disassemble full SEED tapes. SEED headers are skipped, data are stored into station / stream / component files  
check\_seed: checks the contents of miniSEED data files or tapes  
check\_qic: analysis the contents of a Quanterra data tape  
copy\_seed: assembles a full SEED volumes from miniSEED files for a given set of station / stream / component defined in the copy\_seed.cfg configuration file  
make\_dlsv: generates a dataless (header only) SEED volume for a set of station/stream/component defined in copy\_seed.cfg

## **SEED to GSE**

Recently (2009), a SEED to GSE converter was developed at ORFEUS Data Center (ODC), mainly to support the GSE format within AutoDRM at ODC. This tool will become available at the ORFEUS software library.

## **SEISAN**

The SEISAN analysis system has about 40 conversion programs, mostly from some binary format to SEISAN. The SEISAN format can then be converted to any standard format like SEED, SAC or GSE. SEISAN has format converters for most recorders on the market including Kinemetrics, Nanometrics, Teledyne, GeoSig, Reftek, Lennartz, Güralp and Sprengnether.

## **Acknowledgement**

The authors acknowledge with thanks the careful review by Bruce Presgrave of the US Geological Survey. It has improved both the language of the original draft and provided useful references to the Earthworm system. In addition we acknowledge discussion and comments from Lars Ottemöller and Reinoud Sleeman.

| Version | September 2001; DOI: 10.2312/GFZ.NMSOP-2_IS_10.1                                                                                                  |

Below an example is given of an ISF Bulletin which is in accordance with the IMS1.0 format of the International Monitoring System and the current version of the document defining ISF extensions of IMS1.0 (see ISC home page <http://www.isc.ac.uk/standards/isf>).

The example includes two events because an example of only one event would fail to show how consecutive events are to follow each other. The first event is small; with only a few data. This makes it possible to realize the typical way of data presentation at a glance. The second event is larger and this examples shows better how multiple magnitudes and event parameters are to be included.

An example can not, of course, explain which elements are required and which are optional, nor give the units in which each parameter is required to be given. Thus, it is essential for an agency intending to write ISF bulletins to read the format description as well as look at an example. The format description in this case includes the IMS1.0 (a.k.a. GSE2.1) documentation, as well as the extensions of IMS1.0 that constitute the ISF (see IS 10.2). The final ISF description of the extensions document has been posted on the ISC web site (<http://www.isc.ac.uk/standards/isf>) as a PDF document.

In the ISC Bulletin for the time period 01-09-1999 06:00:00 to 01-09-1999 06:45:00 the following 2 events were found:

## 1 Introduction

On the following pages a sample is shown of parameter readings of seismic stations from unassociated arrivals as they were grouped by the National Earthquake Information Center (NEIC) of the USGS in Denver, USA, and reported to the International Data Center (ISC) in Thatcham, UK.

ASCII characters are used as part of the Group and Arrival IDs. According to the IMS1.0 documentation about their data-type "Grouped Arrivals" these characters should help the agency to recognize that several phase arrivals come from the same event but that the reporting station can not locate the event, so they are assigned to the same "group". Note that NEIC uses the groups more restrictively: they only let arrivals share the same group ID if they are at the same station and likely come from the same event. This is within the rules. Examples are, e.g., on page 2 for stations VRAC, TXAR and SLR.

The simple example given below fails to show an important ISF extension, namely the phase information sub-block which allows to give, e.g., for every phase reading, information about what filter was used to do the reading, and so on. This kind of information can now be put, in accordance with the ISF format (see IS10.1) into a "sub-block" that would follow the one shown below and share the same values of arrival ID (column heading ArrID).

The abbreviations used for the different columns are more or less self-explanatory. Column Sta contains the three or four letter station codes and in column Chan the components may be given, in which the parameter reading (time, amplitude, period etc.) was made ( Z – vertical, H – horizontal; N – north and E – east). The column for characterizing the arrival quality (Qual) gives either e (for emergent) or i (for impulsive) onsets and may additionally give the polarity of the first motion (c for compression and d for dilatation). Note that (regrettably) in most cases no channel information is provided by the stations and also amplitudes (Amp) and period readings (Per) are rarely given. Azimuth (Azim) and slowness (Slow) readings are usually reported from seismic arrays only (see, e.g., YKA – Yellowknife Array on page 2). In the column SNR measurements of the signal-to-noise ratio could be reported, which, however, would make sense only with accompanying information in the phase information sub-block about the filter bandwidth. Note, that in some cases the column Author (reporting station or network/array) may also be blank (see page 6).

| Topic   | Seismic station codes – new coding standards                                     |
|---------|----------------------------------------------------------------------------------|
| Authors | IASPEI WORKING GROUP ON STATION CODES<br>Chairman: Ray Buland, retired from USGS |
| Version | August 2008; DOI: 10.2312/GFZ.NMSOP-2_IS_10.3                                    |

## Foreword by the Editor: The IASPEI resolution No. 3 - 2009

At its Scientific Assembly 2009 in Cape Town, South Africa, the International Association of Seismology and Physics of the Earth's Interior (IASPEI) adopted the following resolution:

*“Recognizing that the International Registry of Seismic Stations no longer meets the needs of the seismological community,*

*Recommends adoption of the newly developed seismic network and station coding standards developed by IASPEI to promote compatibility between waveform and parameter data exchange, attribution of parameter data, and flexibility for seismic network operators to better support earthquake monitoring and hazard assessment.*

The resolution is based on the August 2008 report of the IASPEI Working Group on Station Codes, which is reproduced below. The new registry is likely to become operational after some further discussion and testing around 2013.

## 1 Introduction

At the 2006 IASPEI meeting in Santiago, Chile, the Commission on Seismic Observation and Interpretation (CoSOI) Working Group on Seismic Network and Station Codes (WG-SNSC) began discussing how to update the International Registry (IR) of seismic station codes. Although the IR has served the international seismological community well for more than 40 years, it is no longer adequate to meet the evolving needs of network operators and the international data centers. At the 2007 IASPEI meeting in Perugia, Italy, the WG-SNSC approved the main points of the recommendation made in Santiago. On November 11-12, 2007, an *ad hoc* working group with representatives from ISC, NEIC, and EMSC met to discuss the implementation of the recommendation.

The following draft coding standards have been constructed from the recommendations as understood by the WG-SNSC, including comments on the recommendations from the International Federation of Digital Seismograph Networks (FDSN) as well as a number of network operators. In order to achieve the specificity required by the coding standards, the recommendations have been extended as needed. Note that in the following the words “shall” or “must” denotes proposed mandatory standards, while the word “should” denotes strongly recommended (non-mandatory) standards. The word “may” denotes acceptable options for usage.

This document describes how the coding standard would be used to register stations, submit parameter data to data centers, and attribute data summarized in catalogs to the correct agency. General steps and institutional responsibilities for implementing the new coding

standard are also discussed. However, details of the associated software implementation are beyond the scope of this document.

## 2 Coding standards

The location of seismic instrumentation shall be designated by the four fields: *Agency.Deployment.Station.Location*. The specification of a channel in connection with parameter data (e.g., to specify the channel from which a measurement was derived) shall be designated by the five fields: *Agency.Deployment.Station.Location.Channel*. Derived parameters (e.g., picks, amplitudes, hypocenters, magnitudes, etc.) shall be attributed to *Agency* or *Agency.Deployment*.

All fields shall be coded in alphabetic Latin characters (without diacritical marks) and/or Arabic numerals (i.e., characters represented by printable ASCII characters with numerical equivalents less than 128). Non-blank characters in any field shall be left justified and have no imbedded blanks. Non-blank characters in fixed field formats shall be blank padded to the right. All fields shall be case insensitive and have no other restrictions or extensions except as noted in the following. The fields shall be coded as follows:

- Agency: 1-5 alphanumeric characters.
- Deployment: 1-8 alphanumeric characters.
  - Special case: FDSN network codes used as deployment codes shall be case sensitive as required by the SEED v2.4 standard (note that in this case, the agency must be “FDSN”).
- Station: 1-5 alphanumeric characters (this relaxes current International Registry standards, but remains consistent with the SEED v2.4 standard).
- Location: 0-2 alphanumeric characters (e.g., SEED v2.4 compatible).
- Channel: 3 alphanumeric characters following the SEED v2.4 coding standard.

Agencies, deployments, stations, locations, and channels shall be defined in discrete time periods called epochs in the following. Each epoch shall be defined by start and end date-times. The end date-time of the current epoch shall be coded as “undetermined”. The relevant epoch shall be deduced by context (e.g., the date-time of parameter data) and looked up by date-time range rather than explicitly coded as an instance.

## 3 Usage standards

The following usage standards are required or recommended:

- The new coding standards will necessitate a significant revision in the role and operation of the International Registry. However, the ISC and the NEIC, in close cooperation, will continue to act as the central authority for collecting, organizing, and distributing basic seismic station information (e.g., coordinates, owners, operator(s), etc.). This will include tools supporting the simultaneous use of parametric and waveform data (e.g., providing the correspondence between the new coding standard and FDSN nomenclature).

- Scope rules:
  - Agency codes shall be centrally assigned (i.e., guaranteed to be globally unique by the International Registry).
  - Deployment codes shall be created by agencies as needed, but *Agency.Deployment* must be unique at any one time (i.e., duplicated *Agency.Deployment* codes must belong to non-overlapping epochs; see Example 8).
  - Station codes shall be created by agencies as needed, but *Agency.Deployment.Station* must be unique at any one time.
  - Location codes shall be created by agencies as needed, but *Agency.Deployment.Station.Location* must be unique at any one time.
  - The *Agency.Deployment.Station.Location.Channel* designation is intended to be applicable to all types of seismic installations (e.g., fixed and portable seismic networks, seismic arrays, strong motion networks, and strong motion arrays; see Examples 6-9).
- Reporting rules:
  - Deployment, station, location, and channel codes shall be reported to the International Registry for tracking purposes (e.g., to uniquely identify stations and channels and ensure correct attribution in the global bulletins).
    - Channel codes that are unavailable shall be assumed to be SHZ (i.e., short period vertical).
  - Channel codes should be reported along with parametric data to specify the waveform from which the parameters were derived.
  - Latitude, longitude, and elevation associated with each *Agency.Deployment.Station.Location* shall be reported to the International Registry for tracking purposes. Coordinates shall be reported relative to the WGS84 datum (or the actual datum shall be specified). Elevation shall be the elevation at the sensor.
  - Epochs defining the validity of an *Agency.Deployment.Station.Location* designation or changes in associated latitude, longitude, and elevation shall be reported to the International Registry for tracking purposes.
  - Stations, locations, channels, and epochs already documented in a dataless-SEED volume need not be reported separately.
- Usage rules:
  - *Agency.Deployment.Station.Location* shall uniquely identify the location of one or more seismic sensors or, alternatively, one or more seismic channels. This implies that each *Agency.Deployment.Station.Location* shall be associated with one latitude, longitude, and elevation from which parametric data is measured.
    - One *Agency.Deployment.Station.Location* may be used for more than one set of co-located seismic sensors (e.g., seismometers and accelerometers operated by one agency).
    - More than one *Agency.Deployment.Station.Location* may be associated with the same latitude, longitude, and elevation (e.g., to designate co-

located sensors operated by different agencies or to avoid the duplication of channel codes).

- o *Agency.Deployment.Station.Location.Channel* shall uniquely identify one channel associated with a particular sensor. Channels from co-located sensors that have the same names under SEED v2.4 rules shall have different *Agency.Deployment.Station.Location* designations (e.g., typically the location is made different).
- o The following guidelines for assigning station and location codes are recommended:
  - Station and/or location codes may be changed even if sensors have not been moved.
  - Elements of an array may be assigned the same station code and different location codes regardless of the scale of the array (see Example 6).
  - For the convenience of seismic analysts, it is strongly recommended that existing station codes should not be changed more often than absolutely necessary.
  - It is strongly recommended that station and/or location codes should be changed if the associated sensors are moved far enough to result in a significant teleseismic travel-time residual discrepancy (e.g., more than 0.2 s or about 1.2 km).

## 4 Alias standards

Although each *Agency.Deployment.Station.Location* must be associated with a unique latitude, longitude, and elevation, the inverse is not true (or desirable):

- Different *Agency.Deployment.Station.Location* codes may be associated with the same set of sensors (i.e., they are equivalent or aliased):
  - o For compatibility:
    - “FDSN” shall be assigned as an agency code.
      - FDSN network codes are legal deployment codes (although they are a special case because they are case sensitive).
      - When distributing seismic waveform data in FDSN standard SEED or mini-SEED, the FDSN centrally assigned network code shall be used.
        - o Note that there is no intent for *Agency.Deployment* to replace the FDSN network code now or in the future.
      - For correct attribution of parameter data, FDSN.*Network* designations can and should be aliased with the *Agency.Deployment* of the owner/operator (see Example 2).
      - All stations currently registered in the IR shall have an FDSN *Agency.Deployment* alias of FDSN.IR (as well as International Registry *Agency.Deployment* codes of ISC.IR and NEIC.IR; see Example 2).

- o To designate joint ownership/operation:
  - Many stations are owned/operated cooperatively by two or more agencies. Aliasing multiple *Agency.Deployment.Station.Location* codes provides a means for sharing attribution (see Example 4).
- o To designate logical participation:
  - Many stations may be thought of as being part of one or more networks (e.g., IMS) that have no role in owning or operating them (see Example 4).
- Completely separate (i.e., non-aliased) *Agency.Deployment.Station.Location* codes:
  - o Shall be associated with the same latitude, longitude, and elevation to designate co-located sensors operated by different agencies or as part of different deployments (see usage rules above and Example 3).
  - o May be associated with the same latitude, longitude, and elevation to designate co-located sensors operated by the same agency (see usage rules above and Example 7).
  - o Shall be associated with channels from co-located sensors that have the same names under SEED v2.4 rules (see usage rules above).

It is clear that in practice it will be desirable to create aliases at all levels in the *Agency.Deployment.Station.Location.Channel* hierarchy. For example, it may be desirable to alias all stations and locations associated with two or more equivalent *Agency.Deployment* identifiers or it may be desirable to alias all locations associated with two or more equivalent *Agency.Deployment.Station* identifiers. In addition, because aliases may be used for backwards compatibility, to show joint ownership, or to show affiliation with more than one network, it will be necessary to flag the type of each aliases.

## 5 Epoch standards

The following epoch standards are required or recommended:

- Epochs shall be associated with agencies, deployments, stations, locations, channels, and aliases.
- Agency and deployment epochs:
  - o If possible, the start date-time of the earliest epoch should be associated with the creation of the agency or deployment.
  - o Agency and deployment epochs shall be closed when the agency or deployment is terminated or its name is changed.
  - o If an agency or deployment is renamed, a new epoch with the start date-time of the renaming shall be created for the new *Agency.Deployment*.
- Station and location epochs:
  - o If possible, the start date-time of the earliest epoch should be associated with the opening of the station or the installation of equipment at a location.
  - o Station and location epochs shall be closed when the station or location is closed, moved, or renamed.

- If stations or locations have been moved or renamed, new epochs with the new coordinates or names shall be created.
  - For deployments adhering to FDSN rules, station, location, and channel epochs shall be coincident with station and channel epochs documented in the network SEED volumes.
- Alias epochs:
  - Aliases may change with time (e.g., if the agency operating a station changes or the agency changes names). These changes shall be documented in epochs associated with the aliases (see Example 5).
  - Alias epochs shall align with *Agency.Deployment.Station.Location* epochs when possible.

## 6 Display standards

It is expected that the *Agency.Deployment.Station.Location{.Channel}* nomenclature may be used in a variety of ways. The following display standards are recommended:

- Fixed format:
  - Each string should be left justified and blank padded within its field. A null location code should be represented as two blanks.
- Variable format:
  - Represented as a dotted string of the form *Agency.Deployment.Station.Location{.Channel}* with all blanks and trailing dots omitted (see Example 1).

## 7 Agency deployment style guide

The coding standard provides considerable flexibility in assigning agency and deployment codes. However, in creating and discussing the examples (below), it has become clear that some care should be taken in assigning agency codes in particular. For example, it is tempting to think of agencies within a larger organization as deployments (e.g., USGS.NEIC). However, since NEIC can also be considered an agency, this creates confusion and reduces flexibility (because it does not allow for deployments within NEIC).

For this reason, it is strongly suggested that agencies should be organizational units that operate networks or create parameter data. This allows agencies to have multiple network deployments. The fact that an agency may be part of a larger organization will be captured in the description of each agency (e.g., NEIC can be described as the National Earthquake Information Center, US Geological Survey, Department of Interior, US Federal Government).

## 8 Implementation

The ISC and NEIC will work together to implement the revised International Registry. This will include:

- Developing the underlying database structures to support the new coding, epochs, and aliases.
- Populating the new database with the currently registered stations (using the ISC.IR, NEIC.IR, and FDSN.IR deployments).
- Populating the new database with channels currently documented in dataless SEED volumes.
- Working with the seismological agencies and the FDSN to create aliases to existing FDSN network codes.
- Revising web forms to register agencies and report deployments, stations, locations, channels, epochs, and aliases.
- Updating the database from the web form input.
- Making the contents of the new database accessible by means of an interactive (i.e., human) web interface and a software accessible (i.e., program-to-program) network service.
- Developing strategies to attribute parameter data contributed in existing formats to the correct agencies.
- Working with seismic processing system developers to add *Agency.Deployment.Station.Location.Channel* information to contributed parameter data.

## 9 Examples

In the following, the symbol == is used to designate an alias. Note that in the following there are examples of *Agency.Deployment* aliasing, *Agency.Deployment.Station* aliasing, *Agency.Deployment.Station.Location* aliasing, and

*Agency.Deployment.Station.Location.Channel* aliasing. While some attempt has been made to find real-world examples, these examples have been modified as needed to illustrate particular points.

**Example 1 – displaying a null location code:** The US National Earthquake Information Center (NEIC) operates the Advanced National Seismic System (ANSS) Backbone network, which includes station Dugway (DUG). Dugway has only one location, which has a null location code. The station could be designated as NEIC.ANSSBN.DUG. The broadband, high-gain, vertical channel could be designated as NEIC.ANSSBN.DUG..BHZ.

**Example 2 – default aliasing:** The Geological Survey of Canada (GSC) operates the Canadian National Seismograph Network (CNSN), which includes the station Whitehorse (WHY). By default this station might be known as GSC.CNSN.WHY == ISC.IR.WHY ==

NEIC.IR.WHY. If the network had also been assigned an FDSN network code (CN in this case), it would also have aliases of FDSN.CN.WHY and FDSN.IR.WHY

**Example 3 – designating co-located stations:** The Geophysical Institute of Israel (GII) operates the Israeli Seismic Network (ISN), the Israeli Seismic Network Backup (ISNB) and the Israeli Strong Motion Array (ISMA), all of which have sensors located at Eilat (EIL). These sensors might be registered separately as GII.ISN.EIL (== FDSN.IS.EIL), GII.ISNB.EIL, and GII.ISMA.EIL respectively. Note that only one of these stations would be aliased with ISC.IR.EIL, NEIC.IR.EIL, and FDSN.IR.EIL (e.g., with GII.ISN.EIL, but not with GII.ISNB.EIL or GII.ISMA.EIL).

**Example 4 – designating a cooperative station:** The Geophysical Institute of Israel (GII) operates the Israeli Seismic Network (ISN), which includes station Eilat (EIL). EIL is also part of the GeoForschungsZentrum (GFZ) GEOFON network and is station AS48 of the Comprehensive Test Ban Treaty Organization (CTBTO) International Monitoring Network (IMS). These relationships might be shown by aliasing GII.ISN.EIL == GFZ.GEOFON.EIL == CTBTO.IMS.AS48. Note that these aliases may not imply the same sort of relationship (e.g., GII and GFZ may have cooperated in establishing the station, but the GII may only be contributing data to the CTBTO).

**Example 5 – alias epochs:** The University of Utah at Salt Lake City (UUSLC) operates a statewide network, which includes the station San Rafael Swell (SRU). After July 1, 2007, this station became affiliated with the ANSS Backbone network. Therefore, prior to July 1, 2007 the aliasing might have been UUSLC.UU.SRU == FDSN.UU.SRU. After July 1, 2007, the aliasing might be UUSLC.UU.SRU == FDSN.UU.SRU == NEIC.ANSSBN.SRU. That is, a new alias epoch would show that the station was not part of the ANSSBN deployment before July 1, 2007.

**Example 6 – designating an array:** The US National Data Center (USNDC) operates a number of arrays as the US contribution to the Comprehensive Test Ban Treaty Organization (CTBTO). The thirteen elements of the Pinedale (PDAR) array could be designated as CTBTO.USNDC.PD01, CTBTO.USNDC.PD02,... or as CTBTO.USNDC.PDAR.01, CTBTO.USNDC.PDAR.02,... Array elements can be treated as separate stations or as locations of one station, regardless of the separation.

**Example 7 – designating co-located sensors:** The US National Data Center (USNDC) operates a number of arrays as the US contribution to the Comprehensive Test Ban Treaty Organization (CTBTO). The central array element includes co-located broadband and short period sensors. These could be shown as CTBTO.USNDC.PD31..BHZ and CTBTO.USNDC.PD32..SHZ or as CTBTO.USNDC.PD31..BHZ and CTBTO.USNDC.PD31..SHZ. That is, the station codes could follow either the USNDC convention (different station codes for co-located sensors) or the current IR convention.

**Example 8 – designating portable deployments:** Suppose US National Earthquake Information Center (NEIC) portable networks are deployed in Marble, Colorado, USA at two different times. These might both be designated as NEIC.MARBLE in two non-overlapping

epochs (e.g., epoch 1 from 1997-06-15 to 1997-07-02 and epoch 2 from 2001-08-22 to 2002-06-10).

**Example 9 – designating a strong motion array:** Suppose the US National Strong Motion Program (NSMP) deployed a strong motion array in the (fictional) Benz building. The basement sub-array might be designated NSMP.BENZ.BSMT.NE, NSMP.BENZ.BSMT.NW,....

## 11.1 Introduction

Chapter 11 deals with seismogram analysis and extraction of seismic parameter values for data exchange with national and international data centers, for use in research and last, but not least, for informing the public about seismic events. It is mainly written for training purposes and for use as a reference source for seismologists working at observatories, network and analysis centers or with mobile networks for monitoring and analyzing the seismotectonic activity. Complementary, procedures for volcano-seismic monitoring are treated in detail in Chapter 13. However, this Chapter deliberately refers also to classical analog or simple computer assisted interactive procedures and products of seismogram analysis. They are easier to grasp and educationally often more illustrative and appealing. Accordingly we recall with this Chapter also historical aspects of seismic recording and seismogram analysis and provide information and procedures applicable also in the context of education and outreach programs. Thus we hope to address, as the related IRIS program ([http://www.iris.edu/hq/programs/education\\_and\\_outreach](http://www.iris.edu/hq/programs/education_and_outreach)), at least with some sections a wider than specialist audience, including also grade 6-12 students and teachers involved in

“Seismology and Seismographs at Schools”, college students and faculty members, researchers from neighboring disciplines and the public.

Accordingly, the Chapter describes the basic requirements, tools and products of both traditional analog and nowadays almost exclusively digital routine observatory practice, i.e.:

- recognize the occurrence of an earthquake in a record;
- identify and annotate the seismic phases;
- determine onset time and polarity correctly;
- measure the maximum ground amplitude and related period;
- calculate slowness and azimuth;
- determine source parameters such as the hypocenter, origin time, magnitude, etc.

In modern digital observatory practice these procedures are implemented in computer programs. Experience, a basic knowledge of elastic wave propagation (Chapter 2), and the available software can guide a seismologist to analyze large amounts of data and interpret seismograms correctly. Nowadays, in most observatories this work is partially or completely automatized. Earthquake detection, initial P-phase picking, initial localization and magnitude determination are normally carried out by the automatic procedure. Seismologists, using graphical processing and visualization tools, then interactively revise and correct these initial results based on scientific reasoning, ample knowledge and – very important - much practical experience. The aim of this Chapter is to introduce the basic knowledge, data, procedures and tools required for proper seismogram analysis and phase interpretation and to illustrate this with selected seismogram examples. Very rapidly developing new procedures and data products will have to be described in specialized future amendments to this Chapter.

Seismograms reflect the combined influence of the seismic source (Chapter 3), the propagation path (Chapter 2), the frequency response of the recording instrument (Chapter 4, section 4.5 and Chapter 5, section 5.2.8), and the ambient noise at the recording site (Chapter 4, section 4.6). Fig. 11.1 summarizes some essential fields of study and kinds of information which benefit or are largely based on the analysis and interpretation of seismograms. The more completely we interpret the seismograms and the better we quantify the parameters that can be derived therefrom, the better we reveal and understand the structure and properties of the Earth as well as the geometry, kinematics and dynamics of seismic sources and the underlying processes.

Seismograms carry basic information about earthquakes, chemical and nuclear explosions, mining-induced earthquakes, rock bursts and other events generating seismic waves in a very wide range of frequencies from kHz to mHz recorded at distances from a few meters to several 10,000 kilometers from the source (Fig. 11.2).

Seismological data analysis for single stations is nowadays increasingly replaced by network (Chapter 8) and array analysis (Chapter 9). Array-processing techniques have been developed for more than 50 years. Networks and arrays, in contrast to single stations, enable better signal detection and source location. Also, arrays can be used to estimate slowness and azimuth, which allow better phase identification. Further, more accurate magnitude values can be expected by averaging single station magnitudes and for distant sources the signal coherency can be used to determine onset times more reliably. Tab. 11.1 summarizes basic characteristics of single stations, station networks and arrays. In principle, an array can be used as a network and in special cases a network can be used as an array. The most important

differences between networks and arrays are in the degree of signal coherence and the data analysis techniques used.

**Fig. 11.1** Different sub-systems (without seismic noise) which influence a seismic record (yellow boxes) and the information that can be derived from the analysis of seismic records (blue boxes). The ‘\*’ represents the convolution operator.

**Fig. 11.2 Left:** Very weak mining induced seismo-acoustic events with frequencies between about 1 and 100 kHz recorded at distances from meters to decameters in a South African goldmine (cut-out from Figure 2A of Plenkers et al. (2010), Seism. Res. Lett., vol. 81, no. 3, p. 470; © Seismological Society of America; **Right:** Very broadband STS1 record with seismic wave groups from a magnitude 8.2 earthquake in the Kermadec Islands (October 20, 1986) that are superimposed to solid Earth's tides. The mantle Rayleigh wave R7 has traveled almost 130000 km before it was recorded at the station of Nagoya University, Japan (modified from a pamphlet of the Japanese Global Seismology Subcommittee for the POSEIDON project).

**Tab. 11.1** Short characteristic of single stations, station networks and arrays.

|                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Single station</b>  | Classical type of seismic station with its own data processing. Event location only possible by means of three-component records.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| <b>Seismic network</b> | Local, regional or global distribution of stations, physical or ad hoc virtuell, that are as identical as possible, with a common data center and time reference (Chapter 8). Event source parameter estimation (hypocenter, magnitude, mechanism...) is one of the main tasks.                                                                                                                                                                                                                                                                                                                                                        |
| <b>Seismic array</b>   | Cluster of seismic stations with a common time reference and uniform instrumentation. The stations are located close enough to each other in space for the signal waveforms to be correlated between adjacent sensors (Chapter 9). Benefits are: <ul style="list-style-type: none"> <li>• extraction of coherent signals from random noise;</li> <li>• determination of directional information of approaching wavefronts (determination of backazimuth of the source);</li> <li>• determination of slowness and thus of epicentral distance of the source;</li> <li>• event localization by using backazimuth and distance</li> </ul> |

Like single stations, also narrow band-limited seismometer systems loose nowadays increasingly in importance for global monitoring. However, the much easier to handle and cheaper short-period seismographs, which are particularly suitable for local monitoring of weaker events, still outnumber by far the more costly and with respect to environmental effects much more sensitive broadband systems (see <http://www.iris.edu/data/DCProfiles.htm> as well as Chapter 5 and IS 5.4). In any event, bandwidth limitation filters the ground motion, thus distorting the signal shape, the more the narrower the bandwidth. In the extreme it may even shift the apparent onset time and reverse the apparent first-motion polarity (Chapter 4, section 4.5). Most seismological observatories, and especially regional and global networks, are now equipped with broadband seismometers that are able to record signal frequencies between about 0.001 Hz and 50 Hz. The frequency and dynamic range covered by broadband recordings are shown in Figs. 1.9, 4.7 and 11.38 in comparison with classical band-limited analog recordings of the Worldwide Standard Seismograph Network (WWSSN).

A number of classical analog seismograph systems are still in operation at autonomous single stations in some countries. Also, archives are filled with analog recordings of these systems, which were collected over many decades. These data constitute a wealth of information most of which has yet to be fully analyzed and scientifically exploited. Although digital data are superior in many respects, both for advanced routine analysis and even more for scientific research, it will be many years or even decades of digital data acquisition before one may consider the bulk of these old data as no longer needed. However, for the rare big and thus unique earthquakes, and for earthquakes in areas with low seismicity rates, the preservation and comprehensive analysis of these classical and historic seismograms will remain of utmost importance for many years. Around 300,000 paper seismograms, especially those containing large earthquakes, were already scanned and digitized in the IASPEI SeismoArchives Project ([http://www.iaspei.org/downloads/IASPEI\\_SeismoArchives\\_Project\\_summary\\_2011.pdf](http://www.iaspei.org/downloads/IASPEI_SeismoArchives_Project_summary_2011.pdf),

<http://www.iris.edu/seismo/>) but this is still a small fraction of the total amount of analog recordings.

More and more old analog data will be reanalyzed only after being digitized and by using similar procedures and analysis programs as for recent original digital data. Nevertheless, station operators and analysts should still be in a position to handle, understand and properly analyze analog seismograms or plotted digital recordings without computer support and with only modest auxiliary means. Digital seismograms are analyzed in much the same way as classical seismograms, except that the digital analysis uses interactive software which makes the analysis quicker and easier, allows comfortable modification of the time and amplitude resolution of the record plots, modification of the record response and component representation (filtering, record simulation, axes rotation) and to use many other useful operations. But the correct seismogram interpretation requires much of the same knowledge of the appearance of seismic records and of individual seismic phases as the interpretation of classical analog records. The analyst needs to know the typical features in seismic records as a function of distance, depth and source process of the seismic events, their dependence on the polarization of the different types of seismic waves and thus on the azimuth of the source and the orientation of sensor components with respect to it. He/she also needs to be aware of the influence of the seismograph response on the appearance of the record. Without this solid background knowledge, phase identifications and parameter readings may be rather incomplete, systematically biased or even wrong, no matter what kind of sophisticated computer programs for seismogram analysis are used.

Therefore, in this Chapter we will deal first with an introduction to the fundamentals of seismogram analysis at single stations and seismic networks, based on waveform data. Although many decision makers in seismology see nowadays less operational need for this kind of instruction and training, from an educational point of view its importance cannot be overemphasized. An analyst trained in comprehensive and competent analysis of traditional analog seismic recordings, when given access to advanced tools of computer-assisted analysis, will by far outperform any computer specialist with only limited seismological background knowledge.

Automated phase identification and parameter determination have advanced significantly in recent years (Chapter 16) and enjoy massive application at seismological observatories, physical and virtual network centers (Chapter 8) and for seismic arrays (Chapter 9). Only with automation the data from a steadily increasing number of seismic stations can be processed, especially during seismic swarms and aftershock activities. Still, the quality of automatic results might be inferior to those achievable by well-trained analysts (section 11.4). Therefore, an adequate combination of automatic and manual data processing should be assured. Both processing phases and their interaction must be optimized. In many observatories the automatic procedures are only used for fast information to the authorities and the public and run simply in parallel to the manual data processing which intends to produce high quality results for later scientific applications. Therefore, this Manual focusses on providing competent guidance and advice to station operators and seismologists with limited experience on the complexity of seismic waveforms, their comprehensive analysis and interpretation. Moreover, specialists in program development and the automation of algorithms usually also lack the required seismological background knowledge and own rich experience in seismogram analysis. This, however, is an indispensable requirement for further qualification of currently available computer procedures for interactive and automatic data analysis, parameter determination and source location. They have to be in tune both with

older data and established standards to assure long-term data continuity and compatibility and at the same time also assure a broader range of quality observatory products which meet modern research requirements. In this sense, the chapter also addresses the needs of this advanced user community.

Digital recording has the big advantage that the seismic recordings can be reprocessed easily when new processing methods are available. It should also be noted that the falling prices of digital storage media make continuous recording and backup economically feasible. So, new detection algorithms can be applied to the recordings, or the parameters of the algorithms can be tuned by comparing their results with those of human interpretation.

Accordingly, we first give a general introduction to “classical” routine seismogram interpretation which was developed using analog records, respectively waveform plots of digital records at single stations and local or regional seismic networks. Then we discuss both similarities and differences when processing analog or digital data. The basic requirements for parameter extraction, bulletin production as well as parameter and waveform data exchange are also outlined. In the sub-Chapter on digital seismogram analysis we discuss in more detail problems of signal coherence, the related different procedures of data processing and analysis as well as available software for it. The majority of record examples from Germany have been processed with the program Seismic Handler (SHM) developed by K. Stammer which is used for seismic waveform retrieval and data analysis. This program and descriptions are available via <http://www.seismic-handler.org>. Reference is made and examples are given, however, also to/from other analysis software that is widely used internationally, e.g. SEISAN, SeisComp3, Earthworm, SAC and many others (see 11.4). Typical examples of seismic records from different single stations, networks and arrays in different distance ranges (local, regional and teleseismic) and at different source depth are presented, mostly broadband data or filtered records derived therefrom. Special sections are dedicated to the interpretation of seismic core phases (see 11.5.3.3 and 11.5.4).

The treatment of the detailed analysis of teleseismic recordings might provide an interesting, even “exotic” view for readers working at observatories with a high local seismicity where the work is often uniquely focused on the processing of near seismic events. At many networks in areas with complicated crustal structures (e.g., in subduction environments) the locations are normally only carried out with the first P- and S-waves and the high workload due to a strong seismicity does not permit to look for secondary or teleseismic arrivals. But, it should be noted that an understanding of teleseismic records is sometimes very beneficial for local network seismologist too. It happens, for instance, that strong relatively high-frequency teleseismic P or PKP arrivals, under the bad luck of low residuals due to some casual station geometry, are misinterpreted by automatic location procedure as phases from a local or regional event and then a “ghost” earthquake is reported. Another difficulty for automatic and even human interpretation is the recording of two or more seismic events at nearly the same time. This is not so seldom, especially for extended regional networks, and during aftershock or swarm activities in the monitored area. The automatic procedures, which assign the detected phases to earthquake origins, fail occasionally in this situation and then human interaction is necessary.

Since all authors of Chapter 11 come from Germany, the majority of records shown have been collected at stations of the German Regional Seismic Network (GRSN), the Gräfenberg array (GRF) or at other local station networks (Fig. 11.3a). Fig. 11.3b depicts the global distribution of epicenters of seismic events from which record examples are presented.

**Fig. 11.3** **a)** Broadband stations in Germany. Yellow triangles: stations of the German Regional Seismic Network (GRSN) and of the Gräfenberg-Array (GRF). Other triangles: other stations (for details Chapter 8, section 8.7.5). **b)** Global distribution of epicenters of seismic events (red dots: underground nuclear explosions; yellow dots: earthquakes) for which records from the above stations will be presented in Chapter 11 and DS 11.1-11.4.

All GRSN/GRF stations record originally velocity-broadband (BB-velocity) data. All record examples from these stations of short-period (SP), long-period (LP) or BB-displacement seismograms are digitally simulated ones, corresponding to those which would have been

recorded by classical Wood-Anderson, WWSSN-SP, WWSSN-LP, SRO-LP or Kirnos SKD seismographs. Users of this Chapter may feel that the seismograms presented are too much biased towards Europe. Indeed, we may have overlooked some important aspects or typical seismic phases which are well observed in other parts of the world. Therefore, we invite anybody to send valuable complementary data and information to the Editor for integration into revised or amended editions of this electronic Manual.

For routine analysis and international data exchange a standard nomenclature of seismic phases is required. The latest version of the IASPEI Standard Nomenclature of Seismic Phases is given in IS 2.1, together with ray diagrams for most phases. This nomenclature (published earlier in Storchak et al., 2002, 2003 and 2011) partially modifies and complements earlier ones, e.g., that in the last edition of the Willmore (1979) Manual of Seismological Observatory Practice (and in pre-2010 issues of the seismic Bulletins of the International Seismological Centre (ISC). It is more in tune than the earlier versions with the phase definitions of modern Earth and travel-time models (Chapter 2, section 2.7).

The scientific fundamentals of some essential subroutines in seismological analysis software, e.g., on event location and travel-time calculations, are separately treated in annexed material such as IS 11.1, IS 11.3, PD 11.1 and PD 11.2. Complementary tutorials, exercises and information sheets, also suitable for demonstration and practicals in undergraduate courses and “Seismology in Schools” explain in detail basic steps in the interpretation process (e.g., EX 11.1-11.3 and IS 11.6). More related information may be added in the course of future upgrading of this electronic Manual.

## **11.2 Criteria and parameters for routine seismogram analysis**

### **11.2.1 Record duration and dispersion**

The first thing an experienced seismologist looks for when assessing a seismic record is the duration of the signal. Due to the different nature and propagation velocity of seismic waves and the different propagation paths taken by them to a station, travel-time differences between the main wave groups usually grow with distance. Accordingly, the record spreads out in time. The various body-wave groups show no dispersion, so their individual duration remains more or less constant, only the time difference between them changes with distance. The time difference between the main body-wave onsets is roughly  $< 3$  minutes for events at distances  $D < 10^\circ$ ,  $< 16$  min for  $D < 60^\circ$ ,  $< 30$  min for  $D < 100^\circ$  and  $< 45$  min for  $D < 180^\circ$  (Figs. 1.4b, 1.6 and 2.60).

In contrast to body waves, the velocity of surface waves is frequency dependent and thus surface waves are dispersed. Accordingly, depending on the crustal/mantle structure along the propagation path, the duration of Love- and Rayleigh-wave trains increases with distance. At  $D > 100^\circ$  surface wave seismograms may last for an hour or more (Fig. 1.6), and for really strong events, when surface waves may circle the Earth several times, their oscillations on sensitive long-period (LP) or broadband (BB) records may be recognizable over 6 to 12 hours (Fig. 11.2 right). Even for reasonably strong regional earthquakes, e.g.,  $M_s \approx 6$  and  $D \approx 10^\circ$ , the oscillations may be recognizable above the noise level for about an hour although the time difference between the P and S onset is only about 2 min and between P and the maximum amplitude in the surface wave group only 5-6 min. The magnitude dependence of the total earthquake signal duration led the Hungarian seismologist Bisztricsany (1958) to propose a

simple teleseismic procedure for estimating the magnitude of earthquakes that is independent on the knowledge of the distance-dependent amplitude attenuation of different seismic phases and the risk of amplitude clipping of analog records in the case of very strong events.

Finally, besides proper dispersion, scattering may also spread wave energy. This is particularly true for the more high-frequency waves traveling in the usually heterogeneous crust. This gives rise to signal-generated noise and coda waves. Coda waves follow the main generating phases with exponentially decaying amplitudes. The coda duration depends mainly on the event magnitude (Figure 1b in DS 11.1) and only weakly on epicentral distance (Figure 2 in EX 11.1). Thus, record duration can be used for calculating also local coda or duration magnitudes  $M_c$  or  $M_d$  (Chapter 3, section 3.2.4.5).

In summary, signal duration, the time difference between the Rayleigh-wave maximum and the first body-wave arrival (Table 5 in DS 3.1) and in particular the time span between the first and the last recognized body-wave onsets before the arrival of surface waves allow a first rough estimate, whether the earthquake is a local, regional or teleseismic one. This rough classification is a great help in choosing the proper approach, criteria and tools for further more detailed seismogram analysis, source location, and magnitude determination.

## 11.2.2 Key parameters to be measured

### 11.2.2.1 Phase onset time

Onset times of seismic wave groups, first and foremost of the P-wave first arrival, when determined at many seismic stations at different azimuth and at different distance, but also of later arriving phases, are the key input parameter for the location of seismic events (IS 11.1). Travel times published in travel-time tables (such as Jeffreys and Bullen, 1940; Herrin, 1968; Kennett, 1991) and travel-time curves, such as those shown in Figs. 2.48, 2.56 or 2.60 have been derived either from observations or Earth models. They give, as a function of epicentral distance  $D$  and hypocentral depth  $h$ , the differences between *onset times*  $t_{ox}$  (also called *arrival times*) of the respective seismic phases  $x$  and the *origin time*  $OT$  of the seismic source. This time difference is called *travel time*. Onset times mark the first energy arrival of a seismic wave group. The process of recognizing and marking a wave onset and of measuring its onset time is termed *onset time picking*. IS 11.4 provides an elaborated tutorial for both manual and computer assisted consistent picking of phases at local and teleseismic distances and IS 11.5 looks into the problem of picking errors of local phases depending on the signal-to-noise ratio (SNR) as well as on the training and years of experience of analysts and provides a training data set to check analyst performance and the effect of training and gained experience.

The recognition of a wave onset largely depends on the SNR at various frequencies for the given waveform as a whole and the steepness and amplitude of its leading edge. Both are modulated by the shape and bandwidth of the recording seismograph or filter (Figs. 4.9 to 4.13). It is a classical convention in seismological practice to classify onsets, as a qualitative measure for the reliability of their time-picking, as either impulsive (i) or emergent (e). These lower case letters i or e are put in front of the phase symbol. Nowadays, however, with the time resolution and amplitudes and thus the steepness of the waveform flanks being manipulated at will with modern analysis systems, it has become more common to attribute instead a different weight to the picked onset time and polarity readings (see also IS 11.4).

Generally, it is easier to recognize and precisely pick the very first arrival (usually a P wave) on a seismogram than later phases that arrive within the signal-generated coda of earlier waves, often termed “signal-generated noise”.

The relative precision with which an onset can be picked largely depends on the factors discussed above, but the absolute accuracy of onset-time measurement is controlled by the available time reference. Seismic body-wave phases travel rather fast. Their apparent velocities at the surface typically range between about 3 km/s and over 100 km/s (at the antipode the apparent velocity is effectively infinite). Therefore, an absolute accuracy of onset-time picking of less than a second and ideally less than 0.1 s is needed for estimating reliable epicenters (IS 11.1) and determining good Earth models from travel-time data. This was difficult to achieve in earlier decades when only mechanical pendulum clocks or marine chronometers were available at most stations. They have unavoidable drifts and could rarely be checked by comparison with radio time signals more frequently than twice a day. Also, the time resolution of classical paper or film records is usually between 0.25 to 2 mm per second, thus hardly permitting an accuracy of time-picking better than parts of a second. In combination with the limited timing accuracy, the reading errors at many stations of the classical world-wide network, depending also on distance and region, were often two to three seconds (Hwang and Clayton, 1991). However, this improved since the late 1970s with the availability of very-low frequency and widely received time signals, e.g., from the DCF and Omega time services, and recorders driven with exactly 50 Hz stabilized alternating current.

Yet, onset-time reading by human eye from analog records with minute marks led to sometimes even larger errors, a common one being the  $\pm 1$  min for the P-wave first arrival. This is clearly seen in Fig. 2.56 (left), which shows the travel-time picks collected by the ISC from the world-wide seismic station reports between 1964 and 1987. Nowadays, atomic clock time from the satellite-borne Global Positioning System (GPS) is readily available in nearly every corner of the globe. Low-cost GPS receivers are easy to install at both permanent and temporary seismic stations and generally affordable. Therefore the problem of unreliable absolute timing should no longer exist. However, technical problems do occur and one needs to be aware of potential timing problems. In fact, there still are many GPS driven digitizers with wrong timing. Nevertheless, also with high resolution digital data and exact timing now being available it is difficult to decide on the real signal onset, even for sharp P from explosions. Douglas et al. (1997) showed that the reading errors have at best a standard deviation between 0.1 and 0.2 s. However, human reading errors no longer play a major role when digital data are evaluated by means of seismogram analysis software which automatically records with high precision the time at the positions where onsets have been marked with a cursor. Moreover, the recognition of signal onsets and the precision of time picks can be modified easily in the case of digital records within the limits set by the sampling rate and the dynamic range of recording. Both the time and amplitude scales of a record can be compressed or expanded as needed, and task-dependent optimal filters for best phase recognition can be applied as well.

Fig. 11.4 shows such a digital record with the time scale expanded to 12 mm/s. The onset time can be reliably picked with an accuracy of a few tenths of a second. This P-wave first arrival has been classified as an impulsive (i) onset, although it looks emergent in this time-stretched plot. But by expanding the amplitude scale also, the leading edge of the wave arrival becomes steeper and so the onset appears impulsive. This ease with which digital records can be manipulated reduces the representativeness and thus the value of qualitative characterization of onset sharpness by either i or e although there are in fact “e” type of phases where no

change in scaling allows a clear characterization. Alternatively, it has been proposed, therefore, to quantify the *onset-time reliability*. This could be done by reporting, besides the most probable or interpreter-preferred onset time, the estimated range of uncertainty by picking the earliest ( $t_{ox-}$ ) and latest possible onset time ( $t_{ox+}$ ) for each reported phase  $x$ , and of the first arrival in particular (Fig. 11.6 ).

**Fig. 11.4** First motion onset times, phase and polarity readings (c – compression; d – dilatation), maximum amplitude  $A$  and period  $T$  measurements for a sharp (i - impulsive) onset of a P wave from a Severnaya Zemlya event of April 19, 1997, recorded by a broadband three-component single station of the Gräfenberg Array (GRF), Germany but filtered so as to simulate a short-period record of the World-Wide Standard Seismograph Network (WWSSN\_SP).

### 11.2.2.2 Amplitude and period

Whereas the quality, quantity and spatial distribution of reported arrival-time picks largely controls the precision of *source locations* (see IS 11.1), the quality and quantity of amplitude readings for identified specific seismic phases determine the representativeness of amplitude-based event *magnitudes*. The latter are usually based on readings of maximum ground-displacement amplitudes  $A_{\max}$  and related periods for body- and surface-wave groups but for the newly proposed IASPEI broadband magnitude standards  $mB\_BB$  and  $Ms\_BB$  on direct measurement of the maximum ground motion velocity amplitudes  $V_{\max}$  (Chapter 3, sections 3.2.4 and 3.2.5 and IS 3.3). For symmetric oscillations and as general IASPEI measurement standard amplitudes should be given as half peak-to-trough (double) amplitudes. Some computer programs mark the record cycle from which the maximum amplitude  $A_{\max}$  and the related  $T$  have been measured (Figures 3 and 4 in EX 3.1).

However, some algorithms for automatic amplitude measurement prefer maximum zero-to-peak (or trough) measurements instead. In the case of strongly asymmetric phase wavelets the difference may be significant (Fig. 3.19b) but remains always less than 0.3 magnitude units. The related periods were in analog records with limited time resolution traditionally measured as the time between the largest neighboring peaks or troughs, respectively (Fig. 3.19). However, digital data with high time resolution and the use of precise vertical line cursors for time picking in modern analysis tools make it preferable to measure as period twice the time difference between the adjacent maximum peak and maximum trough amplitude, as in Fig. 11.4. This is now the IASPEI recommended measurement standard for

periods (see IASPEI 2013). However, some automatic digital procedures measure zero-to-peak (or trough) amplitude instead and associate with it as period the double time difference between the two adjacent zero crossings related to the maximum positive or negative swing. For a comparison of  $\log(A/T)_{\max}$  and  $\log(V_{\max}/2\pi)$  measurements according to IASPEI standards or to modified automatic procedures see Chapter 3, section 3.2.3.2 and the discussion therein on possible discrepancies.

Note that the measured maximum trace amplitudes in a seismic record have to be corrected for the frequency-dependent magnification of the seismograph to find the “true” ground-motion amplitude at the given period. According to the new IASPEI standards amplitudes should nowadays be measured and reported in nanometers ( $1 \text{ nm} = 10^{-9} \text{ m}$ ), in contrast to the traditional units of micrometers ( $1 \mu\text{m} = 10^{-6} \text{ m}$ ), as in the original amplitude-based magnitude formulas defined in analog days when the seismographs recorded with relatively low magnification. Fig. 3.20 shows a few typical displacement amplification curves of standard analog seismographs used with paper or film records. For digital seismographs, instead of displacement or velocity magnification, the frequency dependent *nominal resolution* is usually given in units of nm/counts, or in  $\text{nm s}^{-1}/\text{count}$  for ground velocity measurements.

Both record amplitudes and related dominating periods do not only depend on the spectrum of the arriving waves but are mainly modulated by the shape, peak magnification and bandwidth of the seismograph or record filter response (e.g., Fig. 4.14). Moreover, the magnifications given in the seismograph response curves are strictly valid only for steady-state harmonic oscillations without any *transient response* (Chapter 4, section 4.5.2). The latter, however, might be significant when narrow-band seismographs record short wavelets of body waves. Signal shape, amplitudes and signal duration are then heavily distorted (Figs. 4.9-4.14 and 4.16-4.19). Therefore, we have written “true” ground motion in quotation marks. Scherbaum (2001 and 2007) gives a detailed discussion of signal distortion which is not taken into account in standard magnitude determinations from band-limited records. However, signal distortion must be corrected for in more advanced digital signal analysis for source parameter estimation by taking into account the full *transfer function* which comprises both the amplitude and the phase response of the seismograph (Chapter 5 and IS 5.2). The distortions are largest for the very first oscillation(s) and they are stronger and longer lasting the narrower the recording bandwidth (Chapter 4, sections 4.5.1 and 4.5.2). Transient response decays with time, depending also on the damping of the seismometer. It is usually negligible for amplitude measurements on dispersed teleseismic surface wave trains.

To calculate real ground motion amplitudes from recorded amplitudes, the frequency-dependent seismometer phase and amplitude response as well as the instrument gain, have to be known from careful calibration (Chapter 5, section 5.6 and IS 5.2). Analog seismograms should be clearly annotated and relate each record to a seismometer with known amplitude response. For digital data, the instrument response is usually included in the header information of each seismogram file or has to be inserted, e.g. in the case of SEED data, by the user or to be given in a separate file that is automatically linked when analyzing data files. As soon as amplitudes and associated periods are picked in digital records, most software tools for seismogram analysis calculate instantaneously the ground displacement or ground velocity amplitudes and write them in related parameter files.

### 11.2.2.3 First-motion polarity

Another parameter which has to be determined (if the SNR permits) and reported routinely is the polarity of the P-wave first motion in vertical component records. Reliable observations of the first motion polarity at stations surrounding the seismic source in different directions allow deriving seismic fault-plane solutions (Chapter 3, section 3.4 and EX 3.2). The wiring of seismometer components has to be carefully checked to assure that compressional (c) first arrivals appear on vertical-component records as an upward motion (+ or U) while dilatational (d) first arrivals are recorded as a downward first half-cycle (- or D). The conventions for horizontal component recordings are + (U) for first motions towards N and E, and – (D) for motions towards S and W, respectively. These need to be taken into account when determining the *backazimuth* of the seismic source from amplitude and polarity readings on 3-component records (see EX 11.2, Figure 1). However, horizontal component polarities are usually not considered in polarity-based fault-plane solutions and therefore not routinely reported to data centers. Fig. 11.4 shows a compressional first arrival.

One should be aware, however, that narrow-band signal filtering may reduce the first-motion amplitude by such a degree that its polarity may no longer be reliably recognized or may even get lost completely in the noise (Figs. 4.9 - 4.11). This may result in wrong polarity reporting and hence erroneous fault-plane solutions. Since short-period (SP) records usually have a narrower bandwidth than medium- to long-period or even broadband records, one should differentiate between first-motion polarity readings from SP and LP/BB records. Also, long-period waves integrate over much of the detailed rupture process and so should show more clearly the overall direction of motion which may not be the same as the first-motion arrival in SP records which may be very small. Therefore, according to recommendations in 1985 of the WG on Telegrafic Formats of the IASPEI Commission on Practice, polarities reported to international data centers should unambiguously differentiate between readings on SP (c and d) and those on LP and BB records (u for “up” = compression and r for “rarefaction” = dilatation). Although event-size and SNR-dependent, polarity readings on BB records tend to be more reliable (Chapter 4, Figs. 4.10 and 4.11). Fig. 11.5 shows short-period P-wave onsets from a Severnaya Zemlya event of April 19, 1997, as recorded in WWSSN\_SP filtered broadband stations of the German Regional Seismic Network (GRSN). The P-wave amplitudes vary significantly within the network, the first-motion polarity remains the same.

**Fig. 11.5** WWSSN\_SP filtered vertical-component broadband records at GRSN stations for the same event as in Fig. 11.4.

### 11.2.3 Advanced wavelet parameter reporting from digital records

The parameters discussed in 11.2.2 have been routinely reported over the decades of analog recording. Digital records, however, allow versatile signal processing so that additional wavelet parameters can be measured routinely. Such parameters may provide a much deeper insight into the seismic source processes and the seismic moment release. Not only can onset times be picked but their range of uncertainty can also be marked. Further, for a given wave group, several amplitudes and related times may be quickly measured and these allow inferences to be drawn on how the rupture process may have developed in space and time. Moreover, the duration of a true ground displacement pulse  $t_w$  and the rise time  $t_r$  to its maximum amplitude contain information about size of the source, the stress drop and the attenuation of the pulse while propagating through the Earth. Integrating over the area underneath a displacement pulse allows to determine its signal moment  $m_s$  which is, depending on the bandwidth and corner period of the recording, related to the seismic moment  $M_0$  (Seidl and Hellweg, 1988). Finally, inferences on the attenuation and scattering properties along the wave path can be drawn from the analysis of wavelet envelopes.

Fig. 11.6 depicts various parameters in relation to different seismic waveforms. One has to be aware, however, that each of these parameters can be severely affected by the properties of the seismic recording system (Fig. 4.17 and Scherbaum 2001). Additionally, one may analyze the SNR and report it as a quantitative parameter for characterizing signal strength and thus of the reliability of phase and parameter readings. This is routinely done when producing the Reviewed Event Bulletin (REB) of the International Data Centre (IDC) in the framework of the CTBTO (Chapter 15). The SNR may be either given as the ratio between the maximum amplitude of a considered seismic phase to that of the preceding ambient noise or signal-generated coda without taking differences in the frequencies into account, by the respective STA/LTA or rms ratio (see IS 8.1) or by determining the spectral SNR (Fig. 11.60). Regrettably, no standard procedure is yet available for best assessment of the quality of phase amplitude and onset-time readings (see also IS 11.4 and section 11.6).

**Fig. 11.6** Complementary signal parameters such as multiple wavelet amplitudes and related times, rise-time  $t_r$  of the displacement pulse, signal moment  $m_s$  and wavelet envelope (with modification from Scherbaum, Of Poles and Zeros, Fig. 1.9, p. 10, © 2001; with permission of Kluwer Academic Publishers).

Although these complementary signal parameters could be determined rather easily and quickly by using appropriate software for signal processing and seismogram analysis, their measurement and reporting to data centers is not yet common practice. It is expected, however, that the recently introduced more flexible formats such as the IASPEI Seismic Format for parameter reporting and storage (see ISF, Chapter 10.2.5), or QuakeML (section 2 in IS 3.2), in conjunction with e-mail and internet data transfer, will pave the way for their routine reporting.

## 11.2.4 Criteria to be used for phase identification

### 11.2.4.1 Travel time and slowness

As outlined in Chapter 2, travel times of identified seismic waves are not only the key information for event location but also for the identification of seismic wave arrivals and the determination of the velocity structure of the Earth along the paths which these waves have traveled. The same applies to the horizontal component  $s_x$  of the slowness vector  $s$ . The following relations hold:

$$s_x = dt/dD = p = 1/v_{app}$$

where  $v_{app}$  is the apparent horizontal velocity of wave propagation,  $dt/dD$  the gradient of the travel-time curve  $t(D)$  in the point of observation at distance  $D$ , and  $p$  is the ray parameter.  $v_{app} = \infty$  for vertical incidence at the surface ( $i = 0^\circ$ ) and  $v_{app} = v =$  true wave propagation velocity for  $i = 90^\circ$ , i.e., when the seismic ray runs along the Earth's surface. The animation linked to section 2.1 of IS 1.1 (New Zealand earthquake 2001) is an excellent example for the slowness differences of the different seismic phases traveling through the GRSN.

Due to the given structure of the Earth, the absolute as well as relative travel-time and slowness differences between various types of seismic waves vary with distance in a systematic way. Therefore, differential travel-time curves with respect to the first P-wave arrival (Figure 4 in EX 11.2) or absolute travel-time curves with respect to known origin time OT (Figs. 2.48 and 2.60) or known slowness-distance relationships (e.g., Fig. 11.7) are very suitable for identifying seismic waves in seismic records. This may be done by matching as many of the recognizable wave onsets in the record as possible with theoretical travel-time or slowness curves for various theoretically expected phases at epicentral distance  $D$ , depending also on source depth  $h$ .

When using analog records with fixed time resolution one should make sure that the plotted  $t(D)$ -curves have the same time-resolution as your record and investigate the match between the theoretical phase travel-times and phase onsets on the records at different distances. Relative travel-time curves thus allow not only the identification of best matching phases but also the distance of the station from the epicenter of the source to be estimated (Fig. 11.8). Note, however, that in certain distance ranges the travel-time curves of different types of seismic waves (Figure 4 in EX 11.2) are close to each other, or even overlap, for example for PP and PcP between about  $40^\circ$  and  $50^\circ$  (see also Figure 6a in DS 11.2) and for S, SKS and ScS between  $75^\circ$  and  $90^\circ$  (Fig. 11.9). Proper phase identification then requires to take besides travel-time differences also additional criteria such as slowness, amplitude, polarity and dominating period into account (sections 11.2.4.2 to 11.2.4.4). The most probable distance should agree best also with those complementary criteria. If absolute travel-time curves or tables are available also the origin time can be estimated (EX 11.1 and EX 11.2).

**Fig. 11.7** The distance-variable horizontal component ray parameter (slowness) of different seismic core phases and the constant slowness of the Pdif phase that is diffracted around the core-mantle boundary (CMB).

**Fig. 11.8** Determination of epicentral distance by searching for the best fit when moving a seismic record from below upward over a differential travel-time curve until one reaches the best possible match of the dominating wave onsets with the travel-time branches of major seismic phases. In the given case the best match was achieved at about 40° distance (1° = 111.2 km).

**Fig. 11.9** Example of long-period horizontal component seismogram sections from a deep-focus earthquake in the Sea of Okhotsk (20.04.1984, mb = 5.9, h = 588 km), recorded at the stations RSSD, RSNY, and RSCP, respectively, in the critical distance range of overlapping travel-time branches of S, SKS and ScS. Because of the large focal depth the depth phase sS is clearly separated in time. Modified cut-out of Plate 40 in Kulhánek (1990), *Anatomy of Seismograms*, p.137-138; © 1990; with permission from Elsevier Science.

Note that the travel-time curves shown in Figs. 11.8 and 2.60 or those given in EX 11.1 and EX 11.2 are valid for near-surface sources only. Both absolute and (to a lesser extent) relative travel times between different phases change with source depth (see IASPEI 1991 Seismological Tables, Kennett, 1991) and, in addition, also depth phases may appear, as in Fig. 11.9 (see also section 2.6.3 in Chapter 2 and Table 1 in EX 11.2). Note also that far-regional travel-time curves ( $D > (17-20^\circ)$ ) vary little from region to region. Typically, the theoretical travel times of the main phases deviate less than 2 s from those observed (compare Figs. 2.57-2.60 in Chapter 2). In contrast, local/regional travel-time curves for crustal and uppermost mantle phases may differ much more from region to region. This is due to the pronounced lateral variations of crust and lithosphere thickness, structure, composition, age and related propagation velocities in continental and oceanic areas. For variations in crustal thickness see Fig. 2.11 in Chapter 2. Therefore, local/regional travel-time curves should be derived for each region in order to improve phase identification and estimates of source distance and depth and thus event location.

Nowadays, rapid epicenter and/or source depth estimates are normally already available at the data center prior to detailed record analysis. Then seismogram analysis software (section 11.4) such as SEISAN (Ottemöller, Voss and Havskov, 2013; Havskov and Ottemöller, 1999; <http://www.ifj.f.uib.no/seismo/software/seisan/seisan.html>), Seismic Handler (SHM) (author: Klaus Stammer, recent developments: Marcus Walther; <http://www.seismic-handler.org>) or SeisComp3 (<http://www.seiscomp3.org/>) allow the theoretically expected travel times for all main seismic phases to be marked on the record. This eases phase identification. An example is shown in Fig. 11.17 for a record analyzed with Seismic Handler. One should be aware, however, that arrival times calculated via ray theory and the appearance of the real wave onsets may differ. Therefore, onset-times of phases, calculated on the basis of a homogeneous 1D global average Earth model via ray theory can only guide the phase identification but should not be used for onset picking! A striking example of possible differences in the order of a few seconds between theoretically expected and really observed phase onsets is shown in Figure 9b of DS 11.3. Realizing this discrepancy led to the improvement of the velocity model for the Earth core in IASP91 (Kennett and Engdahl, 1991) which was taken into account in the AK135 model (Kennett et al., 1995).

Be aware that one of the major challenges for modern global seismology is 3-D tomography of the Earth. We need to know better the location and size of deviations in wave velocity with respect to the global 1-D reference model. Only then will material flows in the mantle and core (which drive plate tectonics, the generation of the Earth's magnetic field and other processes) be better understood. Station analysts should never trust the computer generated theoretical onset times more than the ones that they can recognize in the record itself. For Hilbert transformed phases (see 2.5.4.3) onset times are best read after filtering to correct for the transformation. Without unbiased analyst readings we will never be able to derive improved models of the inhomogeneous Earth. Moreover, the first rapid epicenters, depths and origin-times published by the data centers are only preliminary estimates and are usually based on first arrivals only. Their improvement, especially with respect to source depth, requires more reliable onset-time picks, and the identification of secondary (later) arrivals (Figure 7 in IS 11.1).

At a local array or regional seismic network center both the task of phase identification and of source location of teleseismic events is easier than at a single station because local or regional slowness can be measured from the time differences of the respective wave arrivals at the various stations (Chapter 9 and sections 11.3.4 and 11.3.5 below). But even then, determining D from travel-time differences between P or PKP and later arrivals can significantly improve the location accuracy. This is best done by using three-component broadband recordings from at least one station in the array or network center. The reason is that travel-time differences between first and later arrivals vary more rapidly with distance than the slowness of first arrivals. But large arrays and regional networks usually give better control of the backazimuth of the source than 3-component recordings (compare 11.2.6 and 11.2.7), especially for low-magnitude events recorded at low SNR and thus uncertain first-motion polarity readings.

#### **11.2.4.2 Amplitude-distance relations, dominating periods and waveforms**

Amplitudes of seismic waves vary with distance due to geometric spreading, focusing and defocusing caused by variations of wave speed and attenuation in the Earth. To correctly identify body-wave phases one has first to be able to differentiate between body- and surface-wave groups and then estimate at least roughly, whether the source is at shallow, intermediate or rather large depth. At large distance, surface waves are only seen on LP and BB seismograms. Because of their 2D propagation, geometrical spreading for surface waves is less than for body waves that propagate 3-D. Also, because of their usually longer wavelength, surface waves are less attenuated and less affected by small-scale structural inhomogeneities than body waves. Therefore, on records of shallow seismic events, surface-wave amplitudes dominate over body-wave amplitudes and show less variability with distance (Figs. 11.10 to 11.12). This is also obvious when comparing the magnitude calibration functions for body and surface waves (Figures and tables in DS 3.1).

However, as source depth increases, surface-wave amplitudes decrease relative to those of body waves. The decrease is the larger the shorter the wavelengths. Thus, the surface waves from earthquakes at depth > about 70-100 km may have amplitudes smaller than those of body waves or may not even be detected at all on seismic records (Figure 2 in EX 11.2). This should alert seismogram analysts to look for depth phases, which are then usually well separated from their primary waves and more easily recognizable (Fig. 11.9 above and Figures 6a and b in DS 11.2).

**Fig. 11.10** Approximate smoothed amplitude-distance functions for P and PKP body waves (at about 1 Hz) and of long-period Rayleigh surface waves (LR,  $T \approx 20$  s) for an event of magnitude 4.

**Fig. 11.11** Three-component BB-velocity record at station MOX of a mine collapse in Germany; (13 March 1989;  $M_l = 5.5$ ) at a distance of 112 km and with a backazimuth of  $273^\circ$ . Note the Rayleigh surface-wave arrival LR with subsequent normal dispersion.

**Fig. 11.12** T-R-Z rotated three-component seismogram (SRO-LP filter) from an earthquake east of Severnaya Zemlya (19 April 1997,  $D = 46.4^\circ$ ,  $m_b = 5.8$ ,  $M_s = 5.0$ ). The record shows P, S, SS and strong Rayleigh surface waves with clear normal dispersion. The surface wave maximum has periods of about 20 s. It is called an Airy-phase and corresponds to a minimum in the dispersion curve for continental Rayleigh waves (Fig. 2.10).

Another feature that helps in phase identification is the waveform. Most striking is the difference in waveforms between body and surface waves. Dispersion in surface waves results in long wave trains of slowly increasing and then decreasing amplitudes, whereas non-dispersive body waves form short duration wavelets. Usually, the more long-period surface waves arrive first (“normal” or “positive” dispersion) (as in Figs. 11.11 and 11.12). However, very long-period waves ( $T > 60$  s to about 200 s), that penetrate into the upper mantle down to the asthenosphere (a zone of low wave speeds), may show inverse dispersion. The longest waves then arrive later in the wave train (Figs. 2.20 and 11.15).

For an earthquake of a given seismic moment, the maximum amplitude of the S wave is about five-times larger at source than that of the P waves (Fig. 11.13 left and Figs. 2.4, 2.25, and 2.50). This is a consequence of the different propagation velocities of P and S waves [see Eq. (3.2) in Chapter 3]. Also the spectrum is different for each wave type. Thus, P-wave source spectra have corner frequencies about  $\sqrt{3}$  times higher than those of S. In high-frequency filtered records this may increase P-wave amplitudes with respect to S-wave amplitudes (Fig. 11.13 right). Additionally, the frequency-dependent attenuation of S waves is significantly larger than for P waves (Chapter 2, section 2.5.4.2). Due to both effects, S waves and their multiple reflections and conversions are – within the teleseismic distance range – mainly observed on LP or BB records. On the other hand, the different P-wave phases, such as P, PcP, PKP, and PKKP, are well recorded, up to the largest epicentral distances, by SP seismographs with maximum magnification typically around 1 Hz.

**Fig. 11.13** Left: Low-pass filtered ( $< 0.1$  Hz) and right: band-pass filtered (3.0-8.0 Hz) seismograms of the Oct. 16, 1999, earthquake in California ( $m_b = 6.6$ ,  $M_s = 7.9$ ) as recorded at the broadband station DUG at  $D = 6^\circ$  (courtesy of L. Ottemöller).

Generally, the rupture duration of earthquakes is much longer than the source process of explosions (milliseconds). It ranges from less than a second for small micro-earthquakes up to several minutes for the largest earthquakes with a source which is usually a complex multiple rupture process ( e.g., Figs. 11.14, 3.9 and 3.23 and the animations in sections 2.6 of IS 1.1).

As compared to shallow crustal earthquakes, deep earthquakes of comparable magnitude are often associated with higher stress drop and smaller source dimension. This results in the strong excitation of higher frequencies and thus more simple and impulse-like waveforms (e.g. Figs. 11.15, 2.64, 4.14 and Figures 6a and b in DS 11.2). Therefore, S waves from deep earthquakes may be recognizable even in short-period records at teleseismic distances.

The waveforms of first arriving P waves from underground nuclear explosions (UNE) are in many cases rather impulsive too but associated with comparably small S waves. As compared to shallow earthquakes and when scaled to the same magnitude, the source dimension of an UNE is usually much smaller, their source process simpler and their source duration much shorter (typically in the range of milliseconds). Accordingly, explosions generate significantly more high-frequency energy than earthquakes and usually produce shorter and simpler waveforms of the P first arrivals. However, since their source depths is rather small, typically ranging between several hundred to less than 2000 m, these high frequency waves are prone to scattering and multi-pathing at upper crustal heterogeneities and the near-surface topography, thus producing strong signal-generated coda in local and regional records. Examples of regionally and (less complicated) teleseismically recorded waveforms of underground nuclear explosions are given in Fig. 2.17 and Figures 1 to 5 of DS 11.4, respectively.

**Fig. 11.14** Vertical component records of the P-wave group from a crustal earthquake in Sumatra (04 June 2000;  $m_b = 6.8$ ,  $M_s = 8.0$ ) at the GRSN station MOX at  $D = 93.8^\circ$ . **Top:** WWSSN-SP (type A); **middle:** medium-period Kirnos SKD BB-displacement record (type C), and **bottom:** original BB-velocity record. Clearly recognizable is the multiple rupture process with  $P_4 = P_{\max}$  arriving 25 s after the first arrival P1. The short-period magnitude  $m_b$  determined from P1 would be only 5.4,  $m_b = 6.3$  from P2 and  $m_b = 6.9$  when calculated from P4. When determining the medium-period broadband body-wave magnitude from P4 on the Kirnos record then one gets  $m_B = 7.4$ .

**Fig. 11.15** Very broadband vertical component record of the great  $M_w = 8.2$  deep earthquake ( $h = 609$  km) on 24 May 2013 underneath the Okhotsk Sea at station RUE ( $D = 67.9^\circ$ ), Germany. Note the rather impulsive broadband waveforms of the primary P and S waves and their related depth phases as well as the inverse dispersion of the very long-period mantle surface waves following sSS.

Note, however, that production explosions in large quarries or open cast mines, with yields ranging from several hundred to more than one kiloton TNT, are usually fired in sequences of time-delayed sub-explosions that are spread out over a larger area. Such explosions may generate rather complex wave fields, waveforms and unusual spectra, sometimes further complicated by the local geology and topography, and thus not easy to discriminate from local earthquakes. For discrimination criteria see section 11.2.5.2.

At some particular distances, body waves may have relatively large amplitudes (Fig. 11.10), especially near *caustics* (Figs. 2.30 to 2.33), e.g. for P waves in the distance range between  $15^\circ$  and  $30^\circ$  or around  $D = 145^\circ$  for PKP phases (Figs. 11.10 and 11.72). Due to the caustic around  $145^\circ$  PKP amplitudes are about as large as P-wave amplitudes around  $50^\circ$  epicentral distance (Fig. 11.10). The double triplication of the P-wave travel-time curve between  $15^\circ$  and  $30^\circ$  results in closely spaced successive onsets and consequently rather complex waveforms (Fig. 11.63). In contrast, amplitudes decay rapidly in *shadow zones* due to low-velocity layers (Fig. 2.33). In the teleseismic range this applies to direct P for distances beyond  $100^\circ$  in the so-called *core shadow* due to the drastic decay in P-wave velocity in the outer core as compared to the lower mantle (Fig. 2.79). P is then recorded only as diffracted wave Pdif (Figs. 11.7, 11.10, 2.55, 3.34 and example 2 in DS 11.3). At distances between about  $30^\circ$  and  $100^\circ$ , however, long-period waveforms of P and later phases may look rather simple and well separated (Figs. 11.12, 11.17, 11.20, 11.48, 11.52, and 11.63 as well as Figures 8a, 9c, 10c and 11b in DS 11.2). Beyond the PKP caustic, between  $145^\circ < D < 160^\circ$ , longitudinal core phases split into three travel-time branches with typical amplitude-distance patterns. This, together with their systematic relative travel-time differences, permits rather reliable phase identification and distance estimates, often better than  $1^\circ$  (Figs. 11.73 and 11.74 as well as exercise EX 11.3).

Fig. 11.16 is a simplified diagram showing the relative frequency of later body-wave arrivals with respect to the first P-wave arrival or the number  $n$  of analyzed earthquakes, as a function of epicentral distance  $D$  between  $36^\circ$  and  $166^\circ$ . They are based on observations in standard records (Fig. 3.20 left) of types A4 (SP -  $T < 1.5$  s), B3 (LP -  $T$  between 20 s and 80 s) and C (BB displacement for  $T = 0.1$  s - 20 s) at station MOX, Germany (Bormann, 1972a).

These diagrams show that in the teleseismic distance range one can mainly expect to observe in SP records the following longitudinal phases: P, PcP, ScP, PP, PKP (of branches ab, bc and df), P'P' (= PKPPKP), PKKP, PcPPKP, SKP and the depth phases of P, PP and PKP. In LP and BB records, however, additionally S, ScS, SS, SSS, SKS, SKSP, SKKS, SKKP, SKKKS, PS, PPS, SSP and their depth phases are frequently recorded. This early finding based on the visual analysis of traditional analog film recordings has been confirmed by stacking SP and LP filtered broadband records of the Global Digital Seismic Network (GDSN) (Astiz et al., 1996; Figs. 2.57 to 2.60) and most recently by a refined automatic near real-time envelop stacking procedure developed [at the IRIS Data Management Center \(DMC\) \(Trabant et al., 2012\)](#) (see Fig.11.83).

Since these diagrams or stacked seismogram sections reflect, in a condensed form, some systematic differences in waveforms, amplitudes, dominating periods and relative frequency of occurrence of seismic waves in different distance ranges, they may, when used in addition to travel-time curves and polarization criteria, give some guidance to seismogram analysts as to what kind of phases they may expect at which epicentral distances and in what kind of seismic records or band-pass filter range. Note, however, that the appearance of these phases is not “obligatory” in records of any station. Rather, it may vary from region to region,

depending also on the source mechanisms and the radiation pattern with respect to the recording station, the source depth, the area of reflection (e.g., underneath oceans, continental shield regions, young mountain ranges), and the distance of the given station from zones with frequent deep earthquakes. Therefore, no rigid and globally valid rules for phase identification can be given.

**Fig. 11.16** Relative frequency of occurrence of secondary phases in standard analog records at station MOX, Germany, within the teleseismic distance range 36° to 166°. The first column relates to 100% of analyzed P-wave first arrivals or of analyzed events (hatched column), respectively. In the boxes beneath the phase columns the type of standard records is indicated in which these phases have been observed best or less frequently/clear (then record symbols in brackets). A – short-period; B – long-period LP, C – Kirnos SKD BB-displacement according to the respective standard seismograph types in the Willmore (1979) Manual of Seismological Observatory Practice.

more long-period waves with large amplitudes are generated as well which then dominate also in BB records of local events, as illustrated in Figs. 11.11 and 11.13.

### 11.2.4.3 Polarization

As outlined in sections 2.2 and 2.3 of Chapter 2, P and S waves are linearly polarized, with slight deviations from this ideal in the inhomogeneous and partially anisotropic real Earth (Figs. 2.7 and 2.8). In contrast, surface waves may either be linearly polarized in the horizontal plane perpendicular to the direction of wave propagation (transverse polarization; T direction; e.g., Love waves) or elliptically polarized in the vertical plane oriented in the radial (R) direction of wave propagation (Rayleigh waves; Figs. 2.9, 2.12, 2.15 and 2.16). P-wave particle motion is dominantly back and forth in the direction of wave propagation, whereas S-wave motion is perpendicular to it (Fig. 2.6). Accordingly, a P-wave motion can be split into two main components, one vertical (Z) and one horizontal (R) component (Fig. 2.7). The same applies to Rayleigh waves, but with a 90° phase shift between the Z and R components of motion. S waves, on the other hand, may show purely transverse motion, oscillating in the horizontal plane (SH; i.e., pure T component, as Love waves) or motion in the vertical propagation plane, at right angles to the ray direction (SV), or in any other combination of the two components SH and SV, depending on the source mechanisms and the related radiation pattern (Fig. 3.102). In the latter case S-wave particle motion has Z, R and T components, with SV wave split into a Z and an R component. But depending on the incidence angle and the  $v_p/v_s$  ratio at the station SV may even show elliptical polarization.

Fig. 11.17 shows the good separation of several main seismic phases on a Z-R-T-component plot. At such a large epicentral distance ( $D = 86.5^\circ$ ) the incidence angle (between the seismic ray and the vertical: Fig. 2.7) of P is small (about 15°; see EX 3.3). Therefore, the P-wave amplitude is largest on the Z component whereas for PP, which has a significantly larger incidence angle because of its shallower penetration into the mantle (Fig. 11.65), the amplitude on the R component is almost as large as on Z. For both P and PP no T component is recognizable above the noise. SKS is strong in R and has only a small T component (effect of anisotropy, Fig. 2.8). Depending on source depth and the  $v_p/v_s$  ratio the two phases PS and SP are more or less separated in time with the PS onset being SV polarized and SP as a P phase, both having a strong Z and R component. Love waves (LQ) appear as the first surface waves in T with very small amplitudes in R and Z. In contrast, Rayleigh waves (LR) are strongest in R and Z. SS in this example is also largest in R. From this one can conclude that the S waves generated by this earthquake and radiated into the direction of the recording station are almost purely of SV type. In other cases, however, it is only the difference in the R-T polarization which allows S to be distinguished from SKS (which is SV polarized; see below) in this distance range of around 80° where these two phases arrive closely to each other (Fig. 11.8 and Figure 11 in EX 11.2 where the E-W component agrees in fact with the R component because of the backazimuth of 269°).

**Fig. 11.17** Time-compressed long-period filtered three-component seismogram (SRO-LP simulation filter) of the October 9, 1998, Nicaragua earthquake recorded at station MOX ( $D = 86.5^\circ$ ). Horizontal components have been rotated (ZRT) with R (radial component) in source direction. The seismogram shows long-period phases P, PP, SKS, SP, SS and surface waves L (or LQ for Love wave) and R (or LR for Rayleigh wave).

Thus, when 3-component records are available, the particle motion of seismic waves in space can be reconstructed and used for the identification of seismic wave types (e.g., Vidale, 1986). However, usually the horizontal seismometers are oriented in geographic east (E) and north (N) direction. Then, first the backazimuth of the source has to be computed (see EX 11.2) and then the horizontal components have to be rotated into the horizontal R direction and the perpendicular T direction, respectively. This *axis rotation* is easily performed when digital 3-component data and suitable analysis software are available. It may even be carried one step further by rotating the R and Z component once more, R into the direction of the incident seismic ray (longitudinal L direction) and Z then being perpendicular to it in the Q direction of the SV component. The T component remains unchanged. Such a *ray-oriented co-ordinate system* separates and plots P, SH and SV waves in 3 different components L, T and Q, respectively (Fig. 11.18). These axes transformations are easily made given digital data from arbitrarily oriented orthogonal 3-component sensors such as the widely used triaxial sensors STS2 (Fig. 5.10 and DS 5.1). However, the principle types of polarization can often be quickly assessed even with manual measurement and elementary calculation of the backazimuth from the station to the source from analog 3-component records (see EX 11.2).

**Fig. 11.18** Ray-oriented broadband records (left: Z-N-E components; right: particle motion in the Q-T plane) of the S and SKS wave group from a Hokkaido  $M_s = 6.5$  earthquake on 21 March 1982, at station Kasperske Hory (KHC) at an epicentral distance of  $D = 78.5^\circ$ .

According to the above, all direct, reflected and refracted P waves and their multiples such as

Pg, Pn, PnPn, ...P, pP, PP, pPP, PPP, ...PcP, PKP, PKIKP, PKKP, ...PKPPKP(P'P'), ...

as well as conversions from P to S and vice versa, such as

pS, sP, SP, PS, SPP, ScP, PKS, SKP, SKPPKP, SKKP, SKS, SKKS, ...

have their dominant motion confined to, i.e., are polarized in the Z and R (or L and Q) plane. This applies to all core phases, also to SKS and its multiples, because no shear wave can travel through the liquid outer core and K stands for a longitudinal wave that has traveled through the Earth's outer core and I for a longitudinal wave that has traveled through the Earth's inner core. For ray paths of these waves see Fig. 11.65 and ray plots in IS 2.1.

In contrast, S waves may have both SV and SH energy. However, discontinuities along the propagation path of S waves may act as selective SV/SH filters. Therefore, when an S wave arrives at the free surface, part of its SV energy may be converted into P, thus forming an SP phase. Consequently, the energy reflected as S has a larger SH component as compared to the incoming S. Thus, the more often a mixed SH/SV type of S wave is reflected at the surface, the more it becomes of SH type. Accordingly, SSS, SSSS etc. will show up most clearly or even exclusively on the T component (e.g., Fig. 11.48) unless the primary S wave is dominantly of SV-type (e.g. in Fig. 11.17). As a matter of fact, Love waves are formed through constructive interference of repeated reflections of SH waves at the free surface as well as crustal and upper mantle discontinuities. Similarly, when an S wave hits the core-mantle boundary, part of its SV energy is converted into P which is either refracted into the core with phase name letter K or reflected back into the mantle as P, thus forming the ScP phase. Consequently, multiple ScS is also usually best developed on the T component.

The empirical travel-time curves in Fig. 2.61 (Astiz et al., 1996) summarize rather well, which phases are expected to dominate the vertical, radial or transverse motion in rotated three-component records. If we supplement the use of travel-time curves with seismic recordings in different frequency bands, and take into account systematic differences in

amplitude, frequency content and polarization for P, S and surface waves, and when we know the distances, where caustics and shadow zones occur, then the identification of later seismic wave arrivals is entertaining and like a detective inquiry into the seismic record. It would be regrettable if this art dies out in the age of minimalistic automatic record analysis.

#### 11.2.4.4 Example for documenting and reporting of seismogram parameter readings

Fig. 11.19 shows a plot of the early part of a teleseismic earthquake recorded at stations of the GRSN. At all stations the first arriving P wave is clearly recognizable although the P-wave amplitudes vary strongly throughout the network. This is not a distance effect (the network aperture is less than 10% of the epicentral distance) but rather an effect of different local site conditions related to underground geology and crustal heterogeneity. As demonstrated with Figs. 4.37 and 4.38, the effect is not a constant for each station but depends both on azimuth and distance of the source. It is important to document this. Fig. 11.19 also shows for most stations a clear later arrival about 12 s after P. For the given epicentral distance, no other main phase such as PP, PPP or PcP can occur at such a time (see differential travel-time curves in Fig. 11.8). It is important to pick such later (so-called secondary) onsets which might be “depth phases” (see 11.2.5.1) as these allow a much better determination of source depth than from P-wave first arrivals alone (Figure 7 in IS 11.1).

**Fig. 11.19** WWSSN-SP filtered seismograms at 14 GRSN, GRF, GERES and GEOFON stations from an earthquake in Mongolia (24 Sept. 1998; depth (NEIC-QED) = 33 km; mb = 5.3, Ms = 5.4). Coherent traces have been time-shifted, aligned and sorted according to epicentral distance ( $D = 58.3^\circ$  to BRG,  $60.4^\circ$  to GRA1 and  $63.0^\circ$  to WLF). Note the strong variation in P-wave signal amplitudes and clear depth phases pP arriving about 12 s after P.

Tab. 11.2 gives for the Mongolia earthquake shown in Fig. 11.19 the whole set of parameter readings made at the analysis center of the former Central Seismological Observatory Gräfenberg (SZGRF) in Erlangen, Germany [now: Seismological Central Observatory (SZO) of the BGR in Hannover]:

- first line: date, event identifier, analyst;
- second and following lines: station, onset time, onset character (e or i), phase name (P, S, etc.), direction of first particle motion (c or d), analyzed component, period [s], amplitude [nm], magnitude (mb or Ms), epicentral distance [°]; and
- last two lines: source parameters as determined by the SZGRF (origin time OT, epicentre, average values of mb and Ms, source depth and name of Flinn-Engdahl-region).

Generally, these parameters are stored in a database, used for data exchange and published in lists, bulletins and made available through the Internet (IS 11.2). As an example of station parameter reports grouped according IMS1.0 with ISF1.0 extensions see IS 10.2. The onset characters i (impulsive) should be used only if the time accuracy is better than a few tens of a second, otherwise the onset will be described as e (emergent). Also, when the signal-to-noise-ratio (SNR) of onsets is small and especially, when narrow-band filters are used, the first particle motion should not be given because it might be distorted or lost in the noise. Broadband records are better suited for polarity readings (Figs. 4.10 and 4.11). Their polarities, however, should be reported as u (for “up” = compression) and r (for “rarefaction” = dilatation) so as to differentiate them from short-period polarity readings (c and d, respectively).

**Tab. 11.2** Parameter readings at the SZGRF analysis center for the Mongolia earthquake shown in Fig. 11.19 from records of the GRSN.

**Note:** For this event the international data center NEIC had “set” the source depth to 33 km because of the absence of reported depth phases. The depth-phase picks at the GRSN, however, with an average time difference of pP-P of about 12 s, give - in dependence of the velocity model in the source region - a focal depth of about 44 km. Also note in Tab. 11.2 the large differences in amplitudes (A) determined from the short-period records of individual stations. Accordingly, the station mb estimates vary between 5.4 and 6.2, which cannot be explained by the small differences in epicentral distance. These are mainly station site effects.

## 11.2.5 Criteria to be used in event identification and discrimination

### 11.2.5.1 Discrimination between shallow and deep earthquakes

Earthquakes are often classified on depth as: shallow focus (depth between 0 and 70 km), intermediate focus (depth between 70 and 300 km) and deep focus (depth between 300 and 700 km). However, the term "deep-focus earthquakes" is also often applied to all sub-crustal earthquakes deeper than 70 km. They are generally located in subducting slabs of the lithosphere which are subducted into the mantle. As noted above, the most obvious indication on a seismogram that a large earthquake has a deep focus is the small amplitude of the surface waves with respect to the body-wave amplitudes and the usually rather simple character of the P and S waveforms, which often have impulsive onsets (Fig. 4.15 and Fig. 11.20).

**Fig. 11.20** 3-component Kirnos SKD filtered record at station CLL ( $D = 70.6^\circ$ ) of the October 01, 2013  $M_w = 6.7$  deep earthquake ( $h = 592$  km) underneath the Okhotsk Sea . Note the sharp impulsive body-wave onsets with well-developed depth phases.

In contrast to shallow-focus earthquakes, S phases from deep earthquakes may sometimes be recognizable even in teleseismic short-period records. The body-wave/surface-wave ratio and the type of generated surface waves are also key criteria for discriminating between local earthquakes, which mostly occur at depth larger than 5 km, and quarry blasts, underground explosions or rockbursts in mines, which occur at shallower depth (see 11.2.5.2).

A more precise determination of the depth  $h$  of a seismic source, however, requires either the availability of a seismic network with at least one station being very near to the source, e.g., at an epicentral distance  $D < h$  (because only in the near range the travel time  $t(D, h)$  of the direct P wave varies strongly with source depth  $h$ ), or the identification of seismic *depth phases* in seismic records. The most accurate method of determining the focal depth of an earthquake in routine seismogram analysis, particularly when only single station or network records at teleseismic distances are available, is to identify and read the onset times of depth phases (Chapter 2, section 2.6.3). A depth phase is a characteristic phase of a wave reflected from the surface of the Earth at a point relatively near the hypocenter (Fig. 2.62). At distant seismograph stations, the depth phases pP or sP follow the direct P wave by a time interval

that changes only slowly with distance but rapidly with depth. The time difference between P and other primary seismic phases, however, such as PcP, PP, S, SS etc. changes much more with distance. When records of stations at different distances are available, the different travel-time behavior of primary and depth phases makes it easier to recognize and identify such phases. Because of the more or less fixed ratio between the velocities of P and S waves with  $v_p/v_s \approx \sqrt{3}$  (Chapter 2, section 2.2.3), pP and sP follow P with a more or less fixed ratio of travel-time difference  $t(sP-P) \approx 1.5 t(pP-P)$  (Figs. 11.20 and 11.21). Animations of seismic ray propagation and phase recordings from deep earthquakes are given in files 4, 6 and 9 of IS 11.3.

**Fig. 11.21** Short-period (left) and long-period (right) seismograms from a deep-focus Peru-Brazil border region earthquake on May 1, 1986 ( $m_b = 6.0$ ,  $h = 600$  km) recorded by stations in the distance range  $50.1^\circ$  to  $92.2^\circ$ . Note that the travel-time difference between P and its depth phases pP and sP, respectively, remains nearly unchanged. In contrast PcP comes closer to P with increasing distance and after merging with P on joint grazing incidence at the core-mantle boundary form the diffracted wave Pdif (reprinted from *Anatomy of Seismograms*, Kulhánek, Plate 41, p. 139-140; © 1990; with permission from Elsevier Science).

The time difference between pP and sP and other direct or multiple reflected P waves such as pPP, sPP, pPKP, sPKP, pPdif, sPdif, etc. are all roughly the same. S waves also generate depth phases, e.g., sS, sSKS, sSP etc. The time difference sS-S is slightly larger than sP-P (Figs. 1.10 and 11.20). The difference grows with distance to a maximum of 1.2 times the sP-P time. These additional depth phases may also be well recorded and can be used in a similar way for depth determination as pP and sP.

Given the rough distance between the epicenter and the station, the hypocenter depth ( $h$ ) can be estimated within  $\Delta h \approx \pm 10$  km from travel-time curves or determined by using time-

difference tables for depth-phases (e.g., from  $\Delta t(pP-P)$  or  $\Delta t(sP-P)$ ; see Kennett, 1991 or Table 1 in EX 11.2) or the “rule-of-thumb” in Eq. (11.4) in section 11.2.6.2. An example is given in Fig. 11.22. It depicts broadband records of the GRSN from a deep earthquake ( $h = 119$  km) in the Volcano Islands, West Pacific. The distance range is  $93^\circ$  to  $99^\circ$ . The depth phases  $pP$  and  $pPP$  are marked. From the time difference  $pP-P$  of 31.5 s and an average distance of  $96^\circ$ , it follows from Table 1 in EX 11.2 that the source depth is 122 km. When using Eq. (11.4) instead, we get  $h = 120$  km. This is very close to the source depth of  $h = 119$  km determined by NEIC from data of the global network.

Note that on the records in Fig. 11.22 the depth phases  $pP$  and  $pPP$  have larger amplitudes than the primary  $P$  wave. This may be the case also for  $sP$ ,  $sS$  etc., if the given source mechanism radiates more energy in the direction of the upgoing rays ( $p$  or  $s$ ; Fig. 2.62) than in the direction of the downgoing rays for the related primary phases  $P$ ,  $PP$  or  $S$ . Also, in Fig. 11.22,  $pP$ ,  $PP$  and  $pPP$  have longer periods than  $P$ . Accordingly, they are more coherent throughout the network than the more short-period  $P$  waves. Fig. 11.48 shows for the same earthquake the LP-filtered and rotated 3-component record at station RUE, Germany, with all identified major later arrivals being marked on the record traces. This figure is an example of the search for and comprehensive analysis of secondary phases.

**Fig. 11.22** Broadband vertical-component seismograms of a deep ( $h = 119$  km) earthquake from Volcano Islands region recorded at 17 GRSN, GRF and GEOFON stations. (Source data by NEIC: 2000-03-28 OT 11:00:21.7 UT;  $22.362^\circ\text{N}$ ,  $143.680^\circ\text{E}$ ; depth 119 km; mb 6.8;  $D = 96.8^\circ$  and  $BAZ = 43.5^\circ$  from GRA1). Traces are sorted according to distance. Amplitudes of  $P$  are smaller than  $pP$ . Phases with longer periods  $PP$ ,  $pP$  and  $pPP$  are much more coherent than  $P$ .

Crustal earthquakes usually have a source depth of less than 30 km, so the depth phases may follow their primary phases so closely that their waveforms overlap. Identification and onset-time picking of depth phases is then usually no longer possible by simple routine visual inspection of the record. Therefore, in the absence of depth phases reported by seismic stations, international data centers such as NEIC in its Monthly Listings of Preliminary (or

Quick) Determination of Epicenters often fix the source depth of (presumed) crustal events at 0 km, 10 km or 33 km, as has been the case for the event shown in Fig. 11.19. This is often further specified by adding the capital letter N (for “normal depth” = 33 km) or G (for depth fixed by a geophysicist/analyst). Waveform modeling, however (Fig. 2.85), may enable good depth estimates for shallow earthquakes to be obtained from the best fit of the observed waveforms to synthetic waveforms calculated for different source depth. Although this is not yet routine practice at individual stations, the NEIC has, since 1996, supplemented depth determinations from pP-P and sP-P by synthetic modeling of BB-seismograms. The depth determination is done simultaneously with the determination of fault-plane solutions. This has reduced significantly the number of earthquakes in the PDE listings with arbitrarily assigned source depth 10G or 33N.

Note, however, that often there is no clear evidence of near-source surface reflections in seismic records, or they show apparent pP and sP but with times that are inconsistent from station to station. Douglas et al. (1974 and 1984) have looked into these complexities, particularly in short-period records. Some of these difficulties are avoided in BB and LP recordings. Also, for shallow sources, surface-wave spectra may give the best indication of depth but this method is not easy to apply routinely. Notably, Engdahl et al. (1998) developed an automatic phase identification algorithm, termed EHB for short. It aims at significantly improved hypocenter relocations. EHB is applied to the phase group which immediately follows the P phase at teleseismic distances, including pP, pwP, sP and PcP and allows also the unambiguous identification of later phases such as S. The EHB bulletin is available at the ISC website <http://www.isc.ac.uk/>. The EHB bulletin covers the period 1960-2008 and represented a significant improvement in routine hypocenter determinations made by PDE and ISC before data year 2009, when the ISC implemented a new location algorithm (Bondár and Storchak, 2011). The new ISC location algorithms matches the quality of the EHB bulletin and attempts to obtain a free-depth solution if enough depth resolution is available. Therefore, the ISC would benefit from reports of carefully picked depth phases.

In summary, observational seismologists should be aware that depth phases are vital for improving source locations and making progress in understanding earthquakes in relation to the rheological properties and stress conditions in the lithosphere and upper mantle. Therefore, they should do their utmost to recognize depth phases in seismograms despite the fact that they are not always present and that it may be difficult to identify them reliably. More examples of different kinds of depth phases are given in Figure 6b of DS 11.2 and Figures 1b, 2b, 5b and 7a+b in DS 11.3.

#### **11.2.5.2 Discrimination between natural earthquakes and man-made seismic events**

Quarry and mining blasts as well as controlled explosion charges may excite strong seismic waves. The largest of these events usually have local magnitudes in the range 2 to 4 and may be recorded over distances of several to several thousand kilometers. Rock bursts or collapses of large open galleries in underground mines may also generate seismic waves. The magnitude of these induced seismic events may range from around 2 to 5.5 and their waves may be recorded world-wide (as it was the case with the mining collapse shown in Fig. 11.11). In some countries with low to moderate natural seismicity but a lot of blasting and mining, anthropogenic (so-called “man-made” or “man-induced”) events may form a major fraction of all recorded seismic sources and even outnumber recordings of earthquakes. Then a major seismological challenge is the reliable discrimination of different source types.

According to Figs. 2.38 in Chapter 2 and Figures 4 and 5 in DS 11.4 the amplitude ratio P/S for chemical or underground nuclear explosions is generally larger than for tectonic earthquakes that are dominantly shear fractures. Fig.11.23 shows a comparison of seismograms from: (a) a mining-induced seismic event; (b) a quarry blast; (c) a local earthquake; (d) a regional earthquake. According to (a) and (b) the high-frequency body-wave arrivals are followed, after  $S_g$ , by well-developed lower-frequency and clearly dispersed crustal Rayleigh surface waves ( $R_g$ , with strong vertical components). This is not the case for the two earthquake records (c) and (d) because earthquakes, which are usually more than a few kilometers deep, do not generate short-period fundamental Rayleigh waves of  $R_g$  type. For even deeper (sub-crustal) earthquakes (e.g., Fig. 2.50) only the two high-frequency P- and S- wave phases are recorded within a few hundred kilometers from the epicenter.

**Fig. 11.23** Examples of 3-component seismograms recorded from a: a) mining-induced seismic event ( $D = 80$  km); b) quarry blast explosion ( $D = 104$  km); c) local earthquake ( $D = 110$  km); d) regional earthquake ( $D = 504$  km). Note the different time scales.

Some observatories that record many quarry blasts and mining events, such as the SZGRF, have developed automatic discrimination filters on the basis of such systematic differences in frequency content and polarization. They allow routine separation of such man-made or induced seismic events from tectonic earthquakes. Chernobay and Gabsatarova (1999) give references to many other algorithms for (semi-) automatic source classification. These authors tested the efficiency of the spectrogram and the  $P_g/L_g$  spectral ratio method for routine

discrimination between earthquakes in the Northern Caucasus area of Russia with magnitudes  $< 4.5$  and chemical (quarry) explosions of comparable magnitudes. They showed that no single method can yet assure reliable discrimination between seismic signals from earthquakes and explosions in this region. However, by applying a self-training algorithm, based on hierarchical multi-parameter cluster analysis, almost 98% of the investigated events could be correctly classified and separated into 19 groups of different sources. However, local geology and topography as well as earthquake source mechanisms and applied explosion technologies may vary significantly from region to region. Therefore, there exists no straightforward and globally applicable set of criteria for reliable discrimination between man-made and natural earthquakes, thus requiring specific investigations for different regions.

In this context one should also discuss the discrimination between natural earthquakes (EQ) and underground nuclear explosions (UNE). The Comprehensive Nuclear-Test-Ban Treaty (CTBT) has been negotiated for decades as a matter of high political priority. A Preparatory Commission for the CTBT Organization (CTBTO) has been established with its headquarters in Vienna (<http://ctbto.org>) which is operating an International Monitoring System (IMS; Fig. 15.2 in Chapter 15). Agreement was reached only after many years of demonstrating the potential of seismic methods to discriminate underground explosions from earthquakes, down to rather small magnitudes  $m_b \approx 3.5$  to 4. Thus, by complementing seismic event detection and monitoring with hydro-acoustic, infrasound and radionuclide measurements it is now highly probable that test ban violations can be detected and verified.

The source process of UNEs is simpler and much shorter than for earthquake shear ruptures. Accordingly, P waveforms from explosions are shorter, have higher predominant frequencies, are usually more impulse-like than for earthquakes and expected to have compressional first motions in all directions. Also, UNEs generate lower amplitude S and surface waves than earthquakes of the same body-wave magnitude (Figs. 11.24 and 11.25).

**Fig. 11.24** Broadband displacement records at station Moxa (MOX), Germany of a Jan Mayen earthquake and a Semipalatinsk underground nuclear explosion (UNE) of comparable short-period body-wave magnitude  $m_b$  and at nearly the same distance of about  $40^\circ$ .

**Fig. 11.25** Short-period records at station MOX a) of an underground nuclear explosion at the Semipalatinsk (SPT) test site in Kazakhstan ( $D = 41^\circ$ ) and b) of an earthquake in Afghanistan with comparable magnitude around 6 and at similar distance.

A powerful discriminant is the ratio between short-period P-wave magnitude  $m_b$  and long-period surface-wave magnitude  $M_s$ . The former samples energy around 1 Hz while the latter samples long-period energy around 0.05 Hz. Accordingly, much smaller  $M_s/m_b$  ratios are observed for explosions than for earthquakes (Fig. 11.26). Whereas for a global sample of EQs and UNEs the two populations overlap in an  $M_s/m_b$  diagram, the separation is good when earthquakes and explosions in the same region are considered (e.g., Bormann, 1972c). Early studies have shown that with data of  $m_b \geq 5$  from only one teleseismic station 100% of the observed UNEs with such magnitudes from the Semipalatinsk (SPT) test site could be separated from 95% of the EQs in Middle Asia (Fig. 11.26 left), whereas for the more distant test site in Nevada ( $D = 81^\circ$ ) 95% of the UNEs could be discriminated from 90% of the EQs in the Western USA and Middle America (Fig. 11.26 right).

**Fig. 11.26** Separation of EQs and UNEs by the  $M_s/m_b$  criterion according to data collected at station MOX, Germany. **Left:** for Middle Asia and the test site in Semipalatinsk (SPT); **Right:** for USA/Middle America and the Nevada test site (NTS).

Bowers and Walter (2002) published a similar mb-Ms diagram for US earthquakes and UNE with an average offset of about 0.8 mb units at  $M_s = 5$ , which is comparable with Fig. 11.26 and corresponds to about 6 times larger P-wave amplitudes around 1 Hz for explosions than for earthquakes with the same surface wave magnitude.

Other potential discrimination criteria, such as the different azimuthal distribution of P-wave first-motion polarities expected from UNEs (always +) and EQs (mixed + and -), have not proved to be reliable. One reason is, that due to narrowband filtering, which is applied to reach the lowest possible detection threshold, the P waveform, and particularly the first half cycle, is often so much distorted, that the real first-motion polarity is no longer recognizable in the presence of noise (Figs. 4.10 and 4.11). Detailed investigations also revealed that simplified initial model assumptions about the difference between explosion and earthquake sources do not hold. Surprisingly, the explosion source is poorly understood and source dimensions around magnitude mb  $\approx 4$  seem to be about the same for earthquakes and explosions. Also, many explosions do not approximate to a point-like expansion source in a half-space: significant Love waves may be generated (e.g., by Novaya Zemlya tests in a terrain of rough topography or by triggered tectonic stress release) and many P-wave seismograms show arrivals that cannot be explained (see, e.g., Douglas and Rivers, 1988). Further, it has become clear that much of the differences observed between records of UNEs and EQs are not due to source differences but rather to differences in the geology, topography and seismotectonics of the wider area around the test sites, and that this necessitates the calibration of individual regions (e.g., Douglas et al., 1974).

In summary, one can say that the key criteria to separate EQs and explosions usually work well for large events, however, difficulties come with trying to identify every EQ down to magnitudes around mb = 4 with an average of about 8000 earthquakes of this size per year. It is beyond the scope of this section to go into more detail on this issue. For CTBTO goals and procedures see Chapter 15. State-of-the-art summaries have been published by Bowers and Selby (2009), CTBTO PrepComm, (2009; <http://www.ctbto.org/verification-regime/>), Dahlman et al. (2009), Richards (2002) and Richards and Wu (2011).

### **11.2.6 Quick event identification and location by means of single-station three-component recordings**

Recognizing earthquakes in and locating them by means of seismic records, including also their size classification, are the most important tasks of observatory seismology. Increasingly seismograms are being analyzed at centers that receive the data in (near) real time from networks or arrays of seismometers (Chapters 8 and 9). The seismograms can then be analyzed jointly. This has clear advantages. Nevertheless, some seismic stations are still treated as single station for basic processing. Some of them still record with analog techniques. Yet much can be done even under these “old-fashioned” conditions by the station personnel, provided that at least some form of 3-component recording, either BB or both SP and LP, is available. If these records are in digital form, which is nowadays common, then modern software for digital seismogram analysis will make this task much easier and faster than in the “analog past”. But for most users of ready-made analysis software packages these tools are “black boxes”. Surely, to go through the various steps of analog and graphical location or other related seismological analysis procedures, is much more time consuming. This makes their application unacceptable in modern operational observatory practice. But the

classical analog procedures tell us much more about the underlying principles that are now implemented in algorithmic form in the analysis software. Therefore, those interested in the history of observatory practice but also students in undergraduate Earth science or “Seismology at Schools” courses should have taken note of and practiced them oneself, at least once, to get the necessary “feeling”. The same applies to the sections 11.2.7 on seismic network recordings and 11.2.8 on magnitude determinations, which also give reference to related basic exercises by hand. But all has to start with the single station seismogram analysis.

#### 11.2.6.1 What to do with single station seismograms?

3-component records allow to quickly assess the source type and to roughly estimate the source location and event magnitude. Moreover, later seismic phases can be identified in quite some detail, even if rapid epicenter determinations by international data centers are not available. There would be advantages if, in future, such readings of secondary phases, especially of depth phases, will be reported as early as possible to regional and global data centers so as to enable better depth determinations. Indeed, only recently both NEIC and the ISC introduced more flexible and sophisticated algorithms and the AK135 travel-time model in order to make better use also of secondary phase readings for more reliable hypocenter locations. Locations derived in near real-time usually have not yet well constrained source depths since they are based only on first arriving P and (eventually) S.

It has also been realized that epicentral distances estimated from three-component broadband readings of secondary phases may significantly improve location estimates by small seismic array stations that are based on measurements of the P-wave vector slowness only. The reason is that the travel-time differences between P and later arriving phases, especially of S and SS, vary much more with distance than the first P-wave arrival-time and thus the first P-wave slowness differences at the various stations. Other procedures of modern multi-station (but usually single-component) data analysis are mentioned later *en passant*. Array analysis is discussed in detail in Chapter 9.

How one may proceed when analyzing interactively single station 3C-seismograms without having any prior information about the source and aiming at event location is outlined in EX 11.2 which may be suitable also for demonstration or a practical in “Seismology at Schools” sessions. Additionally, one might look for criteria discussed in sub-section 11.2.5.2 for discriminating between explosions and earthquakes.

If modern broadband digital records are available, which are usually proportional to ground velocity, it is recommended to filter them to produce simulated standard analog Wood-Anderson (WA), WWSSN-SP and -LP seismograms (for responses see Fig. 11.38). Because these types of records are required for proper estimation of the most frequently measured classical types of magnitudes (ML, mb and Ms<sub>20</sub>) according to recently established IASPEI measurement standards (Chapter 3 and IS 3.3) and they may also ease phase identification by mutual inspection. One may also simulate Kirnos SKD BB-displacement and SRO-LP responses (Fig. 11.38) which are particularly suitable for later phase identification in the teleseismic range. This is documented in the following and in DS 11.2 and 11.3 with many record examples. The detailed seismogram analysis might then include phase identification, picking of onset times, amplitudes, periods and polarities, and, if required, also the application of special filters, such as the inverse Hilbert transformation, to phases that have been distorted

by traveling through internal caustics (Chapter 2, section 2.5.4.3), or for identifying phases on the basis of their different polarization.

Of course, in countries with many seismic events recorded every day it will not be possible, particularly for untrained analysts, to apply all these criteria to every recording. On the other hand, this kind of checking takes only a few seconds, minutes at most, for an experienced interpreter who has already trained himself/herself in recognizing immediately the different record patterns on seismograms from systems with standard responses. In addition, many data centers specialize in analyzing only seismograms from local, regional or teleseismic sources. Accordingly, either the number of questions to be asked to the record or the number of signals to be analyzed will be reduced significantly. Also, the task might be significantly eased at observatories or analysis centers which have advanced routines available for digital seismogram analysis such as SEISAN, Seismic Handler (SHM) or SeisComp3. Provided that first hypocenter estimates are already available from international data centers or from own automatic real-time analysis of array or network recordings (e.g., by using SeisComp3), these computer programs allow the theoretical onset times of expected seismic phases to be displayed on the seismogram. However, these theoretical times should not be followed blindly but considered only as assistance. The additional information on amplitudes, frequency content, and polarization has to be taken into account before giving a definite name to a recognizable onset (see 11.2.4 and 11.2.5).

On the other hand, it is meaningless to list more detailed and strict criteria and rules about the appearance and identification of seismic phases in different distance ranges, because they vary from event to event and from source region to source region. They also depend on the specific conditions along the wave-propagation paths and at the recording site. Therefore, every station operator or network analyst has to develop, through experience and systematic data analysis, his/her own criteria for improved seismogram analysis, phase and source identification, and source location. In any event, however, the general approach to record analysis given above should be followed in order to avoid the analysis becoming thoughtless, boring and routine, which would inevitably result in the reporting of inhomogeneous and incomplete low-quality data of little value for research or to the general user.

### **11.2.6.2 3-component hypocenter location**

If well calibrated 3-component broadband and/or long-period recordings are available then it is possible to locate sufficiently strong local events ( $M_l > 3$ ) and teleseismic sources ( $m_b > 5$ ) with an accuracy comparable to or even better than those for un-calibrated arrays or station networks, which, however, should nowadays no longer exist. Yet, this could be demonstrated already some 40 years ago (Bormann, 1971a and b) by using standard film records of type A, B and C (for responses see Fig. 3.20). Amplitudes and onset times were at that time still measured by using an ordinary ruler or a sub-millimeter scaled magnification lens. Nevertheless, the mean square error of epicenters thus located within the distance range  $20^\circ < D < 145^\circ$  was less than 300 km when compared with the epicenter coordinates published by the seismological World Data Centers A and B. This result compares well with the  $4^\circ$  cap location constraint achieved by the fully automatic multi-parameter processing procedure developed by Tong and Kennett (1996) for single 3-component broadband seismograms.

Fig. 11.27 shows the statistical distribution of errors in azimuth and distance based on several hundred 3-component event locations made between 1966 and 1968 at station MOX,

Germany. The errors in epicentral distance estimates, based on reading the S-P times in Kirnos BB records, were in the range  $15^\circ < D < 80^\circ$  in 90% of the cases less than  $\pm 1^\circ$  and in the range  $80^\circ < D < 120^\circ$  also mostly less than about  $\pm 1^\circ$  and rarely greater than  $\pm 2^\circ$ . For  $100^\circ < D < 165^\circ$ , when using in the core shadow of P time differences between other seismic phase arrivals, the errors are somewhat larger, but even then the mean errors seldom differed significantly from zero, and where they did this was usually related to specific source regions, respectively distance/azimuth ranges. This was better than for the automatic Tong and Kennett (2000) procedure for which the authors report that “...in most cases the estimated distances are within the error of 7%.”

**Fig. 11.27 Left:** Errors in backazimuth Az (or BAZ) at station MOX estimated using 3-component records of type A (SP) and of type C (Kirnos SKD BB-displacement). **Right:** Errors in estimating the epicentral distance D at station MOX from records of type C using travel-time difference S-P in the distance range  $10^\circ < D < 100^\circ$  or travel-time differences between other seismic phases for  $D > 100^\circ$ . The solid lines give the 90% confidence interval for the mean error with number of the observations; the dash-dot lines are the 90% confidence interval for a single observation within different distance intervals. Figure according to Bormann (1971b)

When measuring BAZ on short-period records systematic errors may be rather large, reaching up to several tens of degrees (Fig. 11.27 upper left). In contrast, when BAZ is determined on LP or BB records (provided that the magnification of the horizontal components is identical or known with high accuracy) than the BAZ errors are much less, with about 90% probability within  $\pm 10^\circ$  (Fig. 11.27 lower left). Here the Tong and Kennett (1996) results are better, at least for events at distances up to  $100^\circ$ , for which the estimated azimuths were within the error of  $5^\circ$  because of the superior polarization analysis possible with high resolution digital data. The reason for the much larger azimuth errors when using short-period data is obvious from Fig. 2.7 in Chapter 2. The particle motion is complicated in SP records and random due to wave scattering and diffraction by small-scale heterogeneities in the crust and by rough surface topography at or near the station site (see also Buchbinder and Haddon, 1990). In contrast, LP or BB records, which are dominated by longer wavelength signals, usually show simpler P waveforms with clearer first-motion polarity than do SP records.

Taking systematic distance and/or azimuth errors into account, the location accuracy can be improved. Nowadays many seismic arrays and networks use routinely multi-phase epicentral distance determinations for improving their slowness-based source locations. Some advanced software for seismogram analysis like SHM (section 11.4.2) and SEISAN (section 11.4.3 and section 6 in IS 11.6) include this complementary interactive analysis feature. EX 11.2 discusses in detail two examples based on earthquake records made at  $D \approx 20^\circ$  and  $\approx 90^\circ$ . Fig. 11.28 below gives an example for a Pakistan earthquake at  $D = 46.2^\circ$ .

Rough estimates of hypocenter, respectively epicenter distance for shallow seismic sources can be made, however, even in the absence of travel-time tables or curves or related computer programs, when using the following simple “rules-of-thumb” (with  $1^\circ = 111.12 \text{ km}$ ):

$$\text{hypocenter distance } d \text{ [in km]} \approx \Delta t(\text{Sg-Pg}) \text{ [in s]} \times 8 \text{ (near range only)} \quad (11.1)$$

$$\text{epicentral distance } D \text{ [in km]} \approx \Delta t(\text{Sn-Pn}) \text{ [in s]} \times 10 \text{ (in Pn-Sn range } < 15^\circ) \quad (11.2)$$

$$\text{epicentral distance } D \text{ [in } ^\circ] \approx \{\Delta t(\text{S-P}) \text{ [in min]} - 2\} \times 10 \text{ (for } 20^\circ < D < 100^\circ) \quad (11.3)$$

For deep earthquakes one may use another “rule-of-thumb” for a rough estimate of source depth from the travel-time difference  $\Delta t(\text{pP-P})$ :

$$\begin{aligned} \text{source depth } h \text{ [in km]} \approx & \Delta t(\text{pP-P})/2 \text{ [in s]} \times 7 \text{ (for } h < 100 \text{ km)} \\ & \text{or } \times 8 \text{ (for } 100 \text{ km} < h < 300 \text{ km)} \\ & \text{or } \times 9 \text{ (for } h > 300 \text{ km)} \end{aligned} \quad (11.4)$$

The Pakistan earthquake was obviously shallow because it produced a well-developed surface-wave train with amplitudes much larger than the preceding body waves. Moreover, from the travel-time difference of 6.65 min between the identified P and S onset follows according to formula (11.3)  $D = 46.5^\circ$ . This differs only about  $0.3^\circ$  or 33 km from  $D(\text{CLL}) = 46.2^\circ$  calculated by GSR, corresponding to a distance deviation of only 0.065%.

When determining the backazimuth BAZ of the event with respect to the recording station from 3-component records in addition, it is possible to locate the event on a globe or on a suitable map projection. The determination of BAZ by using P-wave first-motion polarity readings has been described in detail in section 3.2 of EX 11.2 and in section 2 of IS 11.1. The insert in the upper right corner of Fig. 11.28 shows the magnified first motion direction of the long-period P-wave onset of the 2013 Pakistan earthquake. One clearly recognizes that the motion in the vertical component goes down, i.e., the ground motion shows in the direction towards the source, in the E-W component it moves with large amplitude up, i.e., the source is located in the East, and the N-S component goes weakly down, i.e., the ground moves also a bit southward. Measuring the correct ground amplitudes in the horizontal components one gets the ratio  $A_S/A_E = 0.262$ . This corresponds to an angle of  $14.7^\circ$  and thus a  $\text{BAZ} = 90^\circ + 14.7^\circ = 104.7^\circ$ .

In contrast, the BAZ to station CLL, when calculated for the more precise epicenter determined on the basis of some hundred P-wave onset-time picks on global seismic network records is  $\text{BAZ} = 101.1^\circ$ , i.e., a deviation of only  $3.7^\circ$  from the 3-component  $\text{BAZ}(\text{CLL})$ . Comparing the two epicenter positions in Fig. 11.28 one can conclude that the location of this event in SE Pakistan has been correctly determined from a single station record more than 5000

km away with a total position difference of only  $2.7^\circ$  or 300 km with respect to the global network location. Thus this 3-component single station location agrees best with the conclusion by Tong and Kennett (1996) that for automatic multi-parameter 3-C broadband locations D estimates are mostly within the error of 7%, azimuths within  $5^\circ$  for  $D < 100^\circ$ , and the locations within a  $4^\circ$  cap.

**Fig. 11.28** Epicenter location of the  $M_w = 7.7$  Pakistan earthquake on 24.09.2013 by the Obninsk data center GSR on the basis of global P-wave onset readings (black star) and by single station 3-component analysis at station CLL, Germany (cyan star), using the travel-time difference S-P for determining D and the long-period P-wave first-motion polarity in Z, E, and N component for determining  $BAZ = \arctan(A_S/A_E) + 90^\circ$ . Plotting single station locations on an epicenter map is a good check that the location is reasonable.

However, also global network epicenter positions may differ up to several 10 km from the true positions due to not accounting for velocity inhomogeneities in the real Earth along the travel paths to the stations (e.g., Engdahl et al., 1998) and also, that the earthquake location itself is not a sharp point but a rupture of finite length which is according to Eq. (3.188) in Chapter 3 for a magnitude  $M = 7.7$  earthquake on average  $L \approx 80$  km.

Bormann (1971a) also showed that in the absence of a sufficiently strong P-wave arrival, the BAZ may also roughly be determined from horizontal components of any later seismic phase which is polarized in the vertical propagation plane, such as PP, PS, PKP or SKS. These phases are often much stronger in BB or LP records than P. However, because of phase shifts on internal caustics (PP, PS, SP, PKPab) the vertical component first motion direction of most of these phases cannot be used reliably for resolving the  $180^\circ$  ambiguity of an azimuth determined from the ratio  $A_E/A_N$  only. However, by considering the inhomogeneous global distribution of earthquake belts, this problem can usually be solved.

In summary, simple 3-component event locations based solely on readings of onset times of identified phases, polarity of P-wave first motions and horizontal component amplitude ratio should proceed as follows:

- general event classification (near/far; shallow/deep;  $D < 100^\circ / > 100^\circ$  etc.);

- picking and identifying the most pronounced phases by comparing the 3-component record traces and related polarization characteristics (Fig. 11.29);
- determination of  $D$  by **a)** matching the identified body-wave phases with either overlays of differential travel-time curves of equal time scale (as in Fig. 11.8 or Figures 2 to 4 in EX 11.2), **b)** measuring their onset-time differences and comparing them with respective distance-dependent differential travel-time tables or by using rules of thumb [see formulas (11.1 to 11.4), **c)** computer calculation of  $D$  based on digital time picks for identified phases and local, regional and/or global travel-time models integrated into the analysis program;
- determination of source depth  $h$  on the basis of identified depth phases (see 11.2.5.1 and Figure 7 with related table in EX 11.2). When knowing  $h$  then correct  $D$  by using either travel-time curves, differential  $t$ - $D$  tables or computer assisted time-picks and comparison with travel-time models;
- determination of the backazimuth (against North) from the station to the source from the first-motion directions in the original Z, N and E component records and from the amplitude ratio  $A_E/A_N$ . For details see Figure 1 and related explanations in EX 11.2;
- determination of the epicenter location and coordinates by using appropriate map projections with isolines of equal azimuth and distance from the station (Figures 5 and 6 in EX 11.2) or by means of suitable computer map projections.

**Fig. 11.29 Left:** Low-pass filtered digital broadband record of the Global Seismograph Network (GSN) station KIV from the shallow ( $h = 10$  km) Greece earthquake of 07 Sept. 1999 ( $m_b = 5.8$ ) at a distance of  $D = 13^\circ$ . Note the clearly recognizable polarity of the first P-wave half-cycle! The record components have been rotated into the directions Z, R and T after determination of the backazimuth from first-motion polarities in Z, N and E ( $BAZ = 134^\circ$ ). Accordingly, P and Rayleigh waves are strongest in Z and R while S and Love (Q) wave are strongest in T. **Right:** The recordings after SP bandpass filtering (0.5-5.0 Hz). The SNR for the P-wave first-motion amplitude is much smaller and their polarity less clear. Also later arrivals required for distance determination are no longer recognizable (signal processing done with SEISAN; courtesy of L. Ottemöller).

Modern computer programs for seismogram analysis include subroutines that allow quick determination of both azimuth and incidence angle from particle motion analysis over the whole waveform of P or other appropriate phases. This is done by determining the direction of the principal components of the particle motion, using, as a measure of reliability of the calculated azimuth and incidence angle, the degree of particle motion linearity/ellipticity. Such an algorithm was available in the SEIS89 software (Baumbach†, 1999). Christoffersson et al. (1988) describe a maximum-likelihood estimator for analyzing the covariance matrix for a single three-component seismogram (see also Roberts and Christoffersson, 1990). The procedure allows joint estimation of the azimuth of approach, and for P and SV waves the apparent angle of incidence and, hence, information on apparent surface velocity and thus on epicentral distance. This has been implemented in the SEISAN software (Havskov and Ottemöller, 1999). Fig. 11.30 shows an example of the application of the software to a portion of the BB recording at Kongsberg (KONO) in Norway for the 12 November 1999, Turkey earthquake ( $M_w = 7.1$ ). The program finds a high correlation (0.9) between the particle motions in the three components, gives the estimate of the backazimuth as  $134^\circ$ , an apparent velocity of 9.6 km/s and the corresponding location of this earthquake at  $40.54^\circ\text{N}$  and  $30.86^\circ\text{E}$ . This was only about 50 km off the epicenter located by the global network.

**Fig. 11.30** Example of azimuth determination and epicenter location of the 12 Nov. 1999 Turkey earthquake by correlation analysis of three-component digital BB records at station KONO, Norway. Backazimuth, apparent velocity, and correlation factor are determined from the P-wave record section marked in the upper figure. For more details see text (signal processing done with SEISAN; courtesy of L. Ottemöller).

The TREMORS Algorithm by Talandier et al. (1991) determines automatically the epicenter of local, regional and teleseismic events based on the 3-component recordings of a single broad-band station. The program was originally developed for the fast tsunami warning in the French South Pacific Islands where network locations are not readily available. The Mantle magnitude  $M_m$  (Okal and Talandier, 1989) is used to characterize the size of the earthquake. An open version of the software was published by Dominique Reymond as part of his Seismic Tool Kit STK (Reymond (2002), <http://seismic-toolkit.sourceforge.net/>).

Applying another algorithms to digital 3-component data from short-period P waves recorded at regional distances, Walck and Chael (1991) show that more than 75% of the records yielded backazimuth within 20° of the correct values. They found, however, a strong dependence on the geological structure. Whereas stations located on Precambrian terrains produced accurate backazimuth for SNR > 5 dB, stations on sedimentary rocks with complicated structure had much larger errors. When excluding these stations, the RMS backazimuth error was only about 6° for recordings with SNR > 10 dB.

Ruud et al. (1988) found that 3-component BB locations for epicenters at distances up to about 1000 km seldom deviated at that time more than 50 km from network solutions, such deviations being mainly due to errors in azimuth estimates. For short-period teleseismic P waves, however, location errors occasionally exceeded 800 km, mainly because of poor distance estimates derived from incidence angles (slowness) alone. For stronger sources, using BB records and distance estimates based on travel-time differences, the location errors were reduced to about 1°.

These quantitative values may no longer be representative when comparing nowadays single station 3-component locations with improved modern network locations. However, the general message still holds, namely that already single station 3-component digital BB data allow reasonably good first location estimates when, for what reasons ever, faster and better network locations are not yet available for the interested user. The suitability of the combined use of seismic array and single 3-component locations had been discussed already by Cassidy et al. (1990).

### **11.2.7 Hypocenter location by means of network and array recordings**

Hypocenter location and origin time determination require at least 4 stations if only first arrival times are read or three stations if independent distance estimates are available from travel-time differences between different phases. The more stations with good SNR (high weighting factor!) are available in local, regional or global networks and the more uniformly these stations are distributed around a seismic source in both azimuth and distance (the latter ranging from close-in to long range) and the more correctly identified and carefully measured seismic phase onsets are used for location, the lower is the uncertainty in these parameter estimates. The procedures in both manual and computer assisted multi-station hypocenter location are outlined in much more detail in IS 11.1, which gives the underlying algorithms and error calculations, as well as standard and advanced methods for both absolute and relative location. Also discussed are the influence of deviations from the assumed Earth models on the locations and the improvement of hypocenter relocations achievable with better Earth models.

Other special problems of seismic event location are dealt with in other information sheets. E.g., IS 7.4 looks into the detectability and earthquake location accuracy modeling of seismic networks, IS 8.5 outlines an authoritative operational location scheme for assessing the quality of automatic network locations, IS 8.6 focusses on the identification and collection of seismic events with accurately known locations (ground truth data) for network calibration and IS 8.7 offers and comments on a tutorial about theoretical and empirical approaches aimed at optimizing network configurations for different seismological tasks.

Array methods of event location are described in Chapter 9. They require that the distance of the source from the array/network is much larger than the array/network aperture (flat wave-front approach) and a high degree of waveform coherence/correlation between the station records. Although seismic arrays are very fashionable, mainly because of their potential for SNR improvement and direct slowness measurements (Fig. 11.45 and sections 11.3.3-11.3.5) there locations may not be superior at all as compared to those of well distributed seismic networks surrounding the source areas. The results may however be improved significantly by investigating and accounting for systematic array or network mislocations due to distance and azimuth dependent slowness anomalies (e.g., Bormann et al., 1992 and Fig. 11.31; Krüger and Weber, 1992; Schweitzer, 2002).

**Fig. 11.31** Comparison of the epicenter locations determined by the GRSN and the Gräfenberg (GRF) and GERES seismic arrays in Germany for a Hindukush earthquake at intermediate depth. QED gives the position of the NEIC/USGS Quick Epicenter Determination based on global network records. The QED location and the epicenters determined by the GRSN with the largest aperture (about 590 km × 700 km), and by the calibrated GRF (aperture about 50 km × 120 km) agree very well (differences less than 100 km). This is not the case for uncalibrated locations of GRF and the very small GERES array (aperture only some 4 km). They are strongly affected by local site anomalies (velocity and/or topographic ones; for GERES see, e.g., Harjes et al., 1994; Bokelmann, 1995) and their locations are about 600-700 km off the QED solution.

In the following we outline for general understanding three basic graphical approaches to locate local seismic events. They all require a “flat Earth” or an “Earth flattening” pre-processing (Fig. 11.32):

1. The **circle and chord method** calculates for each station the hypocentral distance  $d$ , using a known or assumed travel-time model and the relationship  $\mathbf{d} = (\mathbf{t}_S - \mathbf{t}_P) \{(\mathbf{v}_P \cdot \mathbf{v}_S) / (\mathbf{v}_P - \mathbf{v}_S)\}$ . In a crust with mean P-wave velocity of about 5.9 km/s and  $v_S = v_P/\sqrt{3}$  this can be approximated by  $\mathbf{d}$  [in km]  $\approx 8 \cdot \Delta t$  (Sg-Pg) [in s] [see “rule of thumb” (11.1)]. This method is rather insensitive to absolute variations of  $v_P$  and  $v_S$  as long as the ratio  $v_P/v_S$  remains constant.
2. The **circle method** uses only measured P-wave first arrival times at the stations and an assumed reasonable P-wave velocity  $v$ . Circles are drawn around the stations  $n-1$  with radii equal to  $v(\mathbf{t}_n - \mathbf{t}_1)$ ,  $\mathbf{t}_n$  being the P onset time at station  $n$ . The epicenter is then found in the center of the circle which runs through station 1 and touches also the other circles.
3. The **hyperbola method** uses only P-wave arrival time differences between selected station pairs. It requires no à priori knowledge of the P-wave velocity and yields rather good results. For a detailed description of the method and its benefits see Pujol (2004).

**Fig. 11.32** Illustration of the main principles on which graphical location methods are based.

EX 11.1 in this Manual aims at epicenter location by the simple circle and chord method using records from seismic sources both within and outside of a local station network. It is suitable also as a practical for “Seismology at Schools”. First one tries to identify the dominating seismic phase arrivals in the local records of each station by matching them best with the local travel-time curves of Pg, Sg, Pn and/or Sn for a surface focus (Fig. 11.33). This yields at the same time an estimate of the hypocentral distances from the travel-time differences Sg-Pg for each station and of the origin time OT if the assumption of  $h = 0$  is correct (Fig. 11.34). However, when no local/regional travel-time curve is available one may also use as a first approximation the rules of thumb for  $\Delta t(\text{Sg-Pg})$  or  $\Delta t(\text{Sn-Pn})$  [see formulas (11.1-11.3)]. Then it is shown how one can estimate the likely epicenter position by drawing circles around the stations with the so determined station-hypocenter distances and by connecting the crossings of equal pairs of over-shooting circles with so-called straight-line chords (Fig. 11.35).

Finally, it is illustrated that the epicenter position, estimated from the “gravity” center of chord crossings, agrees rather well with the computer solution calculated with the common Geiger (1910 and 1912) algorithm and that additionally the source depth  $h$  can be estimated too by step-wise reduction of the circle radii until the circles all meet for the most likely assumed source depth  $h$  in the epicenter (Fig. 11.35). This iterative search for  $h$  with related modification of the depth-dependent local travel-time curve is also shown as a computer animation in IS 1.1.

**Fig. 11.33** Stepwise movement of a seismic record from left to right over a local travel-time curve for a surface focus until a best fit for three recognizable onsets (Pn, Pg, Sg) and the Lg wave group is achieved, here at a distance  $D \approx 327$  km.

**Fig. 11.34** **Left:** Identified local phases, estimated source origin time and station-source hypocenter distances for an earthquake in the distance range where Pg is the first arrival; **Right:** the same for another seismic event outside of the network in the distance range where Pn is the first arrival ( $d > \text{about } 150$  km).

**Fig. 11.35** Sequence of circle & chord plots for an earthquake in the Vogtland swarm earthquake region, Germany. Assumed are different source depths for fixed hypocentral distances  $d_i$  of the  $i$  stations as calculated from their S-P time differences. For  $h = 13.9$  km the circles cross almost ideally in one point at the epicenter. For details see IS 1.1 and EX 11.1.

Although the results of graphical location principally compare reasonably well with computer assisted locations (see EX 11.3), with the general availability of computers it is nowadays only seldom used in the observatory practice of seismic networks. With digital multi-station data and advanced seismogram analysis software, source location calculation seems to become almost a trivial and very fast completed task. One just picks a sufficient number of first arrival times, activates the relevant location program for local, regional and/or teleseismic sources and gets the result of the iteration process in an instant. Nevertheless, in practice, large location errors or even completely wrong locations can be obtained if certain conditions of the seismic network configuration and the quality of the picked phases are not fulfilled for a certain seismic event. Moreover, up to now most or the location algorithms are run by assuming 1D velocity models. So calculated location errors are not a reliable measure of the true location accuracy. Velocity heterogeneities in real Earth may result in location errors up to several 10 km from the true source, respectively hypocenter location (e.g., Engdahl et al., 1998). These real location errors are the larger the larger the azimuthal gaps are in the station distribution (e.g., Bormann, 1972a and IS 8.5). Reliable assessment of the actual location errors of seismic networks and their used procedures requires comparison with ground truth (GT) data of seismic events with precisely known locations and origin time, such as large chemical or nuclear explosions or precision located events by means of dense local networks with location errors less than about 5 to 10 km (see IS 8.6). For details on location with computer programs and related problems see IS 11.1 and for the program package HYPOSAT/HYPOMOD the PD 11.1.

The accuracy of location, particularly of the source depth, can be significantly improved when at least one of the stations is near to the epicenter at  $D < h$  and/or by picking besides P-wave first arrivals also later arrivals which permit a much better distance and depth control than P-wave slowness data alone. Examples for both local and teleseismic event locations based on seismic network and array data are given in the following sections. IS 11.6 demonstrates the use of the SEISAN software for phase picking, event location and magnitude determination in the local, regional and teleseismic distance range based on seismic records from national and global seismic stations, as well as a 3-component earthquake location. Location using array data is described in Chapter 9, together with the underlying theory. Problems related to the optimization of network configuration aimed at best location results are discussed in detail in IS 8.7 and the PPT tutorial linked to this information sheet.

### **11.2.8 Magnitude determination**

When epicentral distance and depth of a seismic source are (at least roughly) known the magnitude of the event can be estimated. The general procedures to be followed in magnitude determination based on the measurement of amplitudes, periods and/or record duration as well as the specifics of different magnitude scales to be used for local, regional or teleseismic recordings are dealt with in detail in section 3.2 of Chapter 3 on more than 100 pages, including also most recent, still experimental and not yet standardized scales. DS 3.1 presents various classical magnitude calibration functions as diagrams or tables together with other auxiliary material. Some of these classical procedures of magnitude determination can be learnt from EX 3.1, which also gives solutions for the different tasks.

In this context reference has to be made to the most recent

IASPEI resolution on magnitude standards (Fig. 11.36). It relates to classical short-period ML and mb, the traditional NEIC 20s surface-wave magnitude Ms and, most importantly, to the new velocity broadband body and surface-wave standards mB\_B and Ms\_BB. For calculating the moment magnitude Mw from seismic moment M<sub>0</sub> a standard formula has now been fixed too.

**Fig. 11.36** IASPEI resolution 2013 on magnitude measurement standards.

The most recent short-version of the new IASPEI (2013) magnitude measurement standards and nomenclature, IASPEI (2013), can be read and downloaded from the IASPEI website via

[http://www.iaspei.org/commissions/CSOI/Summary\\_WG\\_recommendations\\_20130327.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG_recommendations_20130327.pdf).

IS 3.3 elaborates in detail both on the standard procedures and their comparison with still common classical routines of magnitude determination and results. It also presents the partially modified nomenclature for standard magnitudes and related amplitude measurements and discusses admissible deviations in procedural details, especially in the filter responses to be applied for ML, mb and Ms<sub>20</sub> measurements, provided that the results for identical input data do not differ on absolute values average by more than 0.1 magnitude units.

Possible modifications of recommended standards of amplitude and period measurements in fully automatic procedures are discussed in section 3.2.3.2 of Chapter 3, showing their agreement with results of expert interactive magnitude determinations that strictly adhered to the recommended standards and discussing the reasons for partial disagreement and ways for improving currently available algorithms.

IS 3.4 provides a IASPEI standard magnitude reference data set together with guidelines how to use it for comparison and documentation of currently used magnitude procedures at seismological stations or network analysis centers with the new standards. In this context it is of great importance that all contributors of amplitude and period data for magnitude determination to international data centers, the International Seismological Centre (ISC) in particular, document and report to the ISC in detail their current, or, after they have already introduced the new standards, also their past procedures. This information is crucial for reliable assessment of procedural differences, related systematic biases or random error ranges, respectively of the achieved status of data compatibility and homogeneity and thus of a new level of reliability and representativeness of magnitude data for application and research. A related questionnaire, elaborated by the IASPEI Working on Magnitude Measurement, is attached as Annex 2 to IS 3.4.

Note that the widely used data analysis software packages SEISAN, SHM and SeisComp3 have by 2013 already implemented the related IASPEI recommended simulation filters as default or as auxiliary measurement routines.

## 11.3 Routine signal processing of digital seismograms

Standard analysis includes all data pre-processing and processing operations for the interpretation and inversion of broadband seismograms. Important time-domain processes are signal detection, signal filtering, restitution and simulation, phase picking, polarization analysis as well as beamforming and vespagram analysis for arrays. In the frequency domain the main procedures are frequency-wavenumber (f-k) and spectral analysis. Array-techniques as f-k and vespagram analysis, slowness and azimuth determination for plane waves, and beamforming are discussed in detail in Chapter 9 but a few examples are also shown below. Fourier spectral analysis can be applied to determine the frequency content of transient seismic waves, and power density spectral analysis for estimating the frequency content of seismic noise (Chapter 4 and section 7.2 of Chapter 7).

### 11.3.1 Signal detection

The first task of routine data analysis is the detection of a seismic signal. A signal is distinguishable from the seismic background noise either on the basis of its larger amplitudes or its differences in shape and frequency. Various methods are used for signal detection. Threshold detectors and frequency-wavenumber analysis are applied to the continuous stream of data. In practice, the threshold is not constant but varies with the season and the time of the day. For this reason, the threshold detectors determine the average signal power in two moving time windows: one long term (LTA) and one short term (STA). The ratio of the STA to LTA corresponds to the signal-to-noise-ratio (SNR). For details on the STA/LTA trigger and its optimal parameter setting see IS 8.1 and Chapter 9.

BB records are usually filtered before detectors are used although according to Douglas (1997) a detection algorithm is the better the less filtering is required. Useful filters are Butterworth high-pass filters with corner frequencies  $f_c > 0.5$  Hz or standard band-pass types with center frequency  $f = 1$  Hz for teleseismic P waves and high-pass filter with  $f_c > 1$ -3 Hz for local sources. Fig. 11.37 demonstrates detection and onset-time measurement for a weak, short-period P wave. In the lowermost 30 s segment of a BB-velocity seismogram the oceanic microseisms dominate in the period band 4-7 s. The two other traces are short-period seismograms after narrow band-pass (BP) filtering with: (1) a filter to simulate a WWSSN-SP seismogram; and (2) a two-step Butterworth BP filter of 2<sup>nd</sup>-order with cut-off frequencies of 0.7 and 2 Hz, respectively. The latter filter produces, for the noise conditions at the GRF-array, the best SNR for teleseismic signals. Seismic networks designed to detect mainly local seismic events may require other filter parameters that better account for the difference between local event and local noise frequencies. For optimal detection (see IS 8.1).

Generally, a seismic signal is declared when the STA/LTA exceeds a pre-set threshold. Various procedures, some analytical and some based on personal experience, are used to differentiate between natural earthquakes, mining-induced earthquakes and different kinds of

explosions. Usually, the detected signals are analyzed for routine parameter extraction and data exchange.

**Fig. 11.37** Bandwidth and SNR: A small short-period P-wave arrival below the noise amplitude level on a BB-velocity record (lower trace) may still be recognized by an experienced record analyst because of its much shorter period but missed by a simple amplitude threshold STA/LTA detector. However, by applying a WWSSN-SP simulation filter (middle trace) or a Butterworth band-pass filter (BP; uppermost trace) the SNR can be significantly improved. While the amplitude-based SNR is 0.2 on the original BB record and about 1 on the WWSSN-SP filter it is about 2 on the BP-filtered trace. (Record of an earthquake in the Kurile Islands on 25 March 2002, 6:18:13 UT, recorded at station GRA1, Germany).

### 11.3.2 Signal filtering, restitution and simulation

Classical broadband seismographs, such as the Russian Kirnos SKD, record ground displacement with constant magnification over a bandwidth of 2.5 decades or about 8 octaves (Fig. 11.38 left). The IDA-system (International Deployment of Accelerometers), deployed in the 1970s, used originally LaCoste-Romberg gravimeters for recording long-period waves from strong earthquakes proportional to ground acceleration over the band from DC to about 0.1 Hz (nowadays replaced by STS1-VBB; Fig. 11.38 right). Modern strong-motion sensors such as the Kinematics Inc. Episensor ES-T have a flat response to ground acceleration in an even broader frequency band from DC to 200 Hz. In contrast, feedback-controlled BB sensors for recording weak-motion usually have a flat response proportional to the ground velocity (Fig. 11.38 right). Such BB recordings, however, are often not suitable for direct visual record analysis and parameter extraction in the time domain. Low-frequency signals and surface waves of weak earthquakes are not or only poorly seen. Therefore, BB data must be transformed by applying digital filters in a way that yields optimal seismograms for specific investigations and analysis.

**Fig. 11.38 Left:** Displacement amplitude response characteristics of classical seismographs; **right:** The same for velocity broadband seismographs STS1(GRF) (old version as used at the Gräfenberg array), STS1 (VBB) (advanced version as used in the IRIS global network) and STS2. For STS1 (VBB) and STS2 the detailed response at higher frequencies is not shown (see comment below Tab. 11.4). The classical responses plotted on the left can be simulated with digital data from these broadband systems. Note the different scale of the vertical axes.

For some research tasks and ordinary routine analysis of BB seismograms the application of high-pass, low-pass and band-pass filters is usually sufficient. However, simultaneous multi-channel data processing or the determination of source parameters according to internationally agreed standards (such as body- and surface-wave magnitudes, which are defined on the basis of former analog band-limited recordings) often require simulation of a specific response, including those of classical analog seismograph systems (Seidl, 1980). Another special problem of simulation is “restitution”. Restitution is the realization of a seismograph system whose transfer function is directly proportional to ground displacement, velocity or acceleration in the broadest possible frequency range. The restitution of the true ground displacement down to (near) zero frequencies is a precondition for seismic moment-tensor determinations both in the spectral and the time domain (e.g., signal moment; Fig. 11.6). It is achieved by extending the lowermost corner frequency of the seismometer computationally far beyond that of the physical sensor system. Both the simulation of arbitrary band-limited seismograph systems and the extreme broadband “restitution” of the true ground motion are necessary steps in pre-processing of digital BB data.

Simulation is the mapping of a given seismogram into the seismogram of another type of seismograph, e.g., those of classical analog recordings such as WWSSN-SP, WWSSN-LP, Kirnos SKD, SRO-LP, and Wood-Anderson (WA). Up to now, amplitudes and periods for the determination of body- and surface-wave magnitudes  $m_b$  and  $M_s_{20}$  are measured on simulated WWSSN-SP and WWSSN-LP or SRO-LP seismograms, respectively, and the maximum amplitude for the original local Richter magnitude is measured on Wood-Anderson simulated seismograms. Fig. 11.38 (left) depicts the displacement response of these classical seismographs with smaller bandwidth.

The possibility of carrying out these simulations with high accuracy and stability defines the characteristics that have to be met by modern digital broadband seismograph:

- large bandwidth;
- large dynamic range;
- high resolution;
- low instrumental seismometer self-noise (Chapter 4, section 4.3.2 and Chapter 5, section 5.6.2);
- low noise induced by variations in air pressure and temperature (Chapter 5, sections 5.3.4, 5.3.5, and 7.4.4: for seismometer shielding see IS 5.4);
- analytically exactly known transfer function (see 5.2).

Fig. 11.38 (right) depicts the displacement responses of a few common BB-velocity sensors such as:

- the original Wielandt-Streckeisen STS1 with a bandwidth of 2 decades between the 3-dB roll-off points at frequencies of 0.05 Hz and 5 Hz (anti-aliasing filter). These seismographs were deployed in the world's first broadband array (GRF) around Gräfenberg/Erlangen in Germany (Fig. 11.3a);
- the advanced STS1 that is generally used at the global IRIS network of very broadband (VBB) stations (velocity bandwidth of about 3.3 decades between 5 Hz and 360 s; see also DS 5.1);
- the STS2 seismographs (see DS 5.1) that are usually operated in the frequency range between 0.00827 Hz and 40 Hz (velocity bandwidth of 3.7 decades or about 12 octaves, respectively). They are used at the stations of the GRSN (Fig. 11.3a), deployed world-wide at stations of the GFZ GEOFON network (see <http://www.gfz-potsdam.de/geofon/>) and at many other networks or single stations and have meanwhile also replaced the more narrowband original STS1 at the stations of the GRSN.

All these seismographs can be considered to be linear systems within the range of their usual operation. The transfer function  $H(s)$  of a linear system can be calculated from its poles and zeros by using the following general equation:

$$H(s) = N * \prod (s - z_i) / \prod (s - p_k) \quad (11.5)$$

where  $N$  is the gain factor,  $s = j\omega$  with  $\omega = 2\pi f$  and  $j$  the complex number  $\sqrt{-1}$ ,  $z_i$  are the zeros numbering from  $i = 1$  to  $m$  and  $p_k$  the poles with  $k = 1$  to  $n$ . Zeros are those values for which the numerator in Eq. (11.5) becomes zero while the poles are the values for which the denominator becomes zero.

Tab. 11.3 summarizes the poles and zeros of the classical standard responses WWSSN-SP, WWSSN-LP, WA (Wood-Anderson), Kirnos SKD and SRO-LP which control the shape of the response curves and Tab. 11.4 gives the poles and zeros for the three broadband responses shown in Fig. 11.38 on the right. Not given are the gain factors because they depend on the specific data acquisition system and its sensitivity.

**Note:** The poles and zeros in this tables are for WWSSN-SP, WWSSN-LP, WA (Wood-Anderson) close but not identical with those of the respective standard responses of these seismographs as now recommended by the IASPEI-CoSOI Working Group on Magnitude Measurements (Figure 1 and accompanying text in IS 3.3 ).

**Tab. 11.3** Zeros and poles corresponding to the displacement transfer functions depicted in Fig. 11.38 left for the classical analog standard seismographs WWSSN-SP, WWSSN-LP, WA, Kirnos SKD and SRO-LP (according to K. Stammer, personal communication 2013).

| Seismograph | Zeros                                                                                                                         | Poles                                                                                                                                                                                                                                                                                  |

**Comment:** The detailed characteristics of the STS2 at high-frequencies depends on the production date. There are three different generations available, shown here is the first generation of STS2. In most cases high frequencies of 40 Hz or more are not relevant. Then a simple approximation of the STS2 transfer function, as STS2-approx in Tab. 11.4, is sufficient. When high frequencies are important and are close to the Nyquist frequency (e.g. for 100 Hz sampled data the Nyquist frequency would be 50 Hz) then also the characteristics of the digitizer has to be taken into account. In order to prevent aliasing digitizers one should apply steep low-pass filters just below the Nyquist frequency, usually represented as cascades of FIR filters with dozens of FIR coefficients per stage. Details on FIR filters can be found in Scherbaum and Bouin (2007).

Using the data given in these tables, the exact responses of the respective seismographs can be easily found. As an example, we calculate the response curve of the WWSSN-SP. According to Tab. 11.3 it has three zeros and four poles. Thus we can write Eq. (11.5) as

$$H(s) = N * s^3 / (s-p_1)(s-p_2)(s-p_3)(s-p_4) \quad (11.6)$$

with

$$\begin{aligned} p_1 &= -3.3678 - 3.7315j \\ p_2 &= -3.3678 + 3.7315j \\ p_3 &= -7.0372 - 4.5456j \\ p_4 &= -7.0372 + 4.5456j. \end{aligned}$$

The squared lower angular corner frequency of the response (that is in the given case the eigenfrequency of the WWSSN-SP seismometer) is  $\omega_l^2 = p_1 \cdot p_2$  whereas the squared upper angular eigenfrequency (which used to be in the classical SP records that of the galvanometer) is  $\omega_u^2 = p_3 \cdot p_4$ . Since the product of conjugate complex numbers  $(a + bj)(a - bj) = a^2 + b^2$  it follows for the poles:

$$\begin{aligned} \omega_l^2 &= 25.27 & \text{with } f_l &= 0.80 \text{ Hz} & \text{and} \\ \omega_u^2 &= 70.18 & \text{with } f_u &= 1.33 \text{ Hz}. \end{aligned}$$

When comparing these values for the corner frequencies of the displacement response of WWSSN-SP in Fig. 11.38 (left) one recognizes that the maximum displacement magnification (slope approximately zero) lies indeed between these two values. Further, as outlined in EX 5.6, a conjugate pair of poles such as  $p_1$  and  $p_2$  or  $p_3$  and  $p_4$  correspond to a second order corner of the amplitude response, i.e., to a change in the slope of the asymptote to the response curve by 2 orders. Moreover, the number of zeros controls the slope of the response curve at the low-frequency end, which is three in the case of the WWSSN-SP (see Eq. (11.6) and Tab. 11.3). Thus, at its low-frequency end, the WWSSN-SP response has according to its three zeros a slope of 3. This changes at the first pair of poles, i.e., at  $f_l = 0.8$

Hz, by 2 orders from 3 to 1 (i.e., to velocity proportional), and again at  $f_u = 1.33$  Hz by two orders from 1 to  $-1$ . This is clearly seen in Fig. 11.38.

In the same manner, the general shape of all the responses given in that figure can be assessed or precisely calculated according to Eq. (11.5) by using the values for the poles and zeros given in Tabs. 11.3 and 11.4. Doing the same with the values given in Tab. 11.3 for WWSSN-LP one gets for  $f_l = 0.06667$  Hz, corresponding to the 15 s seismometer and  $f_u = 0.009998$  Hz corresponding to the 100 s galvanometer, used in original WWSSN-LP seismographs. The aim of the exercise in EX 5.5 is to calculate and construct with the method shown above the responses of seismographs operating at several seismic stations of the global network from the data given in their SEED header information and EX 5.6 outlines this in detail for the calculation of the response of WWSSN-LP.

When comparing poles and zeros in Tab. 11.3 for WWSSN-SP with those given in Table 1 of IS 3.3 for the respective IASPEI standard response than one realizes that the former has besides the 3 zeros two conjugate poles whereas the latter has two conjugate and three single poles. Single poles mean, however, that at their respective frequency the response slope changes not by two but only by one order. But since the standard WWSSN-SP has three single poles instead of the second conjugate pole, the standard response (Figure 1 in IS 3.3) decays steeper towards higher frequencies than the WWSSN-SP response in Fig. 11.38 left. But the response slope towards longer periods, which is of third order and controlled by the number of zeros, is identical in both cases. The slight difference in response shape, however, results in a slight difference of amplitude-period measurements, which make mb(IASPEI) on average 0.033 m.u. smaller than mb(BGR) (Figure 11 in section 5.1.2 of IS 3.3). This is still acceptable within the IASPEI magnitude standard requirements as long as the absolute average differences for magnitudes of the same type but measured with different procedures is  $< 0.1$  m.u.).

Note that the poles and zeros given in Tabs. 11.3 and 11.4 are valid only if the input signal to the considered seismographs is ground displacement (amplitude  $A_d$ ). Consequently, the values in Tab. 11.3 are not suitable for simulating the responses of the classical seismographs if the input signal to the filter is not displacement. From the output of the STS2, any simulation filter gets as an input a signal, which is approximately velocity-proportional within the frequency range between 0.00827 Hz and 40 Hz. In this range its amplitude is  $A_v = \omega A_d$ . Accordingly, the transfer function of the simulation filter  $H_{fs}(s)$  has to be the convolution product of the inverse of the transfer function  $H_r(s)$  of the recording instrument and the transfer function  $H_s(s)$  of the seismograph that is to be simulated:

$$H_{fs}(s) = H_r^{-1}(s) * H_s(s). \quad (11.7)$$

Thus, even for the same  $H_s(s)$  to be simulated, the poles and zeros of the simulation filter differ depending on those of the recording seismograph. Tab. 11.5 gives, as an example from the SZ0, the poles and zeros of the displacement filters for simulating the responses shown in Fig. 11.38 (left), and the poles and zeros given in Tab. 11.4, from output data of the STS2-approx.

**Tab. 11.5** Poles and zeros of the simulation filters required for simulating standard seismograms of WWSSN-SP, WWSSN-LP, WA, Kirnos SKD and SRO-LP, respectively, from the SZO STS2-approx BB-velocity records (according to K. Stammli, personal communication 2013).

| Simulation filter | Zeros                                                                                                                                    | Poles                                                                                                                                                                                                                                                                                      |

If one wishes, however, to simulate accurately the WWSSN-SP response in Fig. 11.38 left only in the frequency range of interest for this type of seismograph, namely about 0.1 to 10 Hz in which the STS seismographs yield a perfect velocity-proportional output signal, then the simulation filter would just require one zero less but the same two conjugate poles as in Tab. 11.3.

Fig. 11.39 shows a comparison of the original three-component BB-velocity record of an STS2 at station WET from a local earthquake in Germany with the respective seismograms of a simulated Wood-Anderson (WA) seismograph. For a teleseismic earthquake Fig. 11.40 gives the STS2 BB-velocity record together with the respective simulated records for WWSSN-SP and LP. Figs. 11.41 and 11.42 give two more examples of both record simulation and the restitution of very broadband (VBB) true ground displacement. VBB restitution of ground displacement is achieved by convolving the given displacement response of the recording seismometer with its own inverse, i.e.,:

$$H_{\text{rest}}(s) = H_s^{-1}(s) * H_s(s). \quad (11.8)$$

However, Eq. (11.8) works well only for frequencies smaller than the upper corner frequency (anti-alias filter!) and for signal amplitudes that are well above the level of ambient, internal (instrumental), and digitization noise.

**Fig. 11.39** 3-component recordings at station WET (Wettzell) of a local earthquake at an epicentral distance of  $D = 116$  km. Lower traces: original STS2 records with sampling rate of 80 Hz; upper traces: simulated Wood-Anderson (WA) recordings. Note that the displacement-proportional WA record contains less high frequency oscillations than the velocity-proportional STS2 record (compare responses shown in Fig. 11.38).

**Fig. 11.40** BB-velocity seismogram (top) and simulated WWSSN-SP (middle) and WWSSN-LP seismograms (bottom). Note the strong dependence of waveforms and seismogram shape on the bandwidth of the simulated seismographs.

Both Fig. 11.39 and 11.40 clearly show the strong influence of differences in bandwidth and center frequencies of the seismometer responses on both the individual waveforms and the general shape of the seismogram. This is particularly obvious in the simulated teleseismic records of Fig. 11.41 showing the teleseismic P-wave group of an earthquake in California on 16 Sept. 1999. In the BB-velocity seismogram one recognizes clearly the superposition of a

low-frequency signal and a high-frequency wave group. The latter is clearly seen in the WWSSN-SP record but is completely absent in the SRO-LP simulation. From this comparison it is obvious that both the BB-velocity and the SP seismograms enhance short-period signal amplitudes. Therefore, only the former recordings are well suited for studying the fine structure of the Earth and determining the onset time and amplitude of short-period P waves. In contrast, BB-displacement seismograms and LP- filtered seismograms suppress the high-frequencies in the signals. Generally they are more suited to routine practice for surface-wave magnitude estimation and for the identification of most (but not all!) later phases (Figs. 11.16, 11.17, 11.48 and Fig. 2.52).

**Fig. 11.41** From top to bottom: The original BB-velocity seismogram recorded at station GRFO; the BB-displacement record derived by restitution; the simulated WWSSN-SP; and the simulated SRO-LP seismograms of the P-wave group from an earthquake in California (16 Sept. 1999;  $D = 84.1^\circ$ ;  $M_s = 7.4$ ).

Fig. 11.42 shows 10-days of a VBB record from an STS1 vertical-component seismograph (corner period  $T_c = 360s$ ) at station MOX and simulated WWSSN-SP and SRO-LP seismograms for a short (40 min) time segment of this VBB record.

**Fig. 11.42** STS1 ( $T_c = 360s$ ) vertical-component seismogram with a length of 10 days (upper trace) as recorded at MOX station, Germany. In the seismogram we recognize Earth's tides and different earthquakes as spikes. For one of these earthquakes a WWSSN-SP and SRO-LP simulation filter was applied (lower traces). The length of the filtered records is 40 minutes.

Figs. 11.43a-d demonstrate, with examples from the GRSN, the restitution of (“true”) displacement signals from BB-velocity records as well as the simulation of WWSSN-SP, Kirnos BB-displacement and SRO-LP records. All traces are time-shifted for the P-wave group and summed (they are aligned on trace 16). The summation trace forms a reference seismogram for the determination of signal form variations. Generally, this trace is used for the beam (see 11.3.5 below). The different records clearly demonstrate the frequency dependence of the spatial coherence of the signal. Whereas high-frequency signals are incoherent over the dimension of this regional network (aperture about 500 to 800 km) this is not so for the long-period records which are nearly identical at all recording sites.

The following features are shown in Figs. 11.43a-d:

- a) Time shifted BB-displacement (traces 16-30) and BB-velocity seismograms (traces 1-15) with a duration of 145 s of the P-wave group from an earthquake in Peru on 23 June 2001 ( $M_s = 8.1$ ) as recorded at 15 stations of the GRSN. The BB-displacement seismogram suppresses the high-frequencies, which are clearly shown on the BB-velocity record.
- b) WWSSN-SP simulations for the same stations as in Figure 11.43a. The high-frequency signals are relatively enhanced by the short-period bandpass but the shape and amplitudes of the waveforms are shown to vary considerably within the network, i.e., the coherence is low.
- c) Kirnos SKD BB-displacement and d) SRO-LP simulations for the same stations as in Fig.11.43a. The high-frequency signals are masked. All traces show coherent waveforms.

**Fig. 11.43a** (for explanation see preceeding text)

**Fig. 11.43b** As Fig. 11.43a however with short-period WWSSN-SP simulation.

**Fig 11.43c** As Fig. 11.43a but for displacement-proportional Kirnos SKD simulation.

**Fig. 11.43d** As Fig. 11.43a but for long-period SRO-LP simulation.

**Fig. 11.43a-d** Restitution, simulation and coherency of seismograms demonstrated with records of the GRSN from an earthquake in Peru (23 June 2001,  $M_s = 8.1$ ) in the epicentral distance range from  $96^\circ$  to  $100^\circ$ ; for explanation see text).

### 11.3.3 Signal coherency at networks and arrays

Heterogeneous crustal structure and the array aperture limit the period band of spatially coherent signals. The larger the aperture of an array the more rapidly the signal coherence falls off with frequency. At short periods the array behaves like a network of single stations whereas at long periods the array behaves like a sensitive single station. For the GRF-array (aperture about 50 to 120 km) for instance, the signals are coherent for periods between about 1 and 50 s. For the GRSN the band of coherent signals is at longer periods than for the small aperture detection arrays like GERES in Germany or NORES in Norway (aperture 4 and 3 km, respectively) where signals are coherent at periods shorter than 1 s. In the coherency band itself, waveforms vary depending on their dominant frequency, apparent horizontal velocity and azimuth of approach. For instance, coherent waveforms are observed from the GRSN for BB-displacement records, Kirnos SKD simulation and all long-period simulated seismograms (Figs. 11.43a-d) whereas for simulated WWSSN-SP seismograms the waveforms have low coherence or are incoherent.

Figs. 11.44a and b show a comparison of the first 14 s of a P-wave group recorded by the GRSN and the GRF-array. The coherence is clearly higher in the short-period range for the recordings at the smaller GRF-array than for the GRSN. The GRSN works as an array for periods longer than about 10 s but it is a network for shorter periods where the GRF-array works as an array down to periods of about 1 s. This discussion is valid for teleseismic signals only, where the epicentral distance is larger than the aperture of the station network or array.

**Fig. 11.44a** (Figure caption below)

**Fig. 11.44b** (Figure caption below)

**Fig. 11.44** WWSSN-SP simulations of the first 14 s after the P-wave onset from the same Peru earthquake as in Fig. 11.43. **a)** Recordings at the GRSN. **b)** Recordings at the GRF array. Note the lower coherence of the waveforms recorded at the stations of the regional network, which has an aperture much larger than the GRF-array (Fig. 11.3a). The summation traces 17 and 14, respectively, are reference seismograms for the determination of signal waveform variations.

### 11.3.4 Beamforming

Beamforming improves the SNR of a seismic signal by summing the coherent signals from array stations (see 9.4.5). Signals at each station are time shifted by the delay time relative to some reference point or station. The delay time depends on ray slowness and azimuth and can be determined by trial and error or by f-k analysis (see 11.3.5). The delayed signals are summed “in phase” to produce the beam. In delay-and-sum beamforming with  $N$  stations the SNR improves by a factor  $\sqrt{N}$  if the noise is uncorrelated between the seismometers. In the summation the increase in amplitude of the coherent signal is proportional to  $N$ . For incoherent waves (random seismic noise in particular), it is only proportional to  $\sqrt{N}$ . Thus, beamforming and f-k analysis are helpful for routine analysis if very weak signals have to be detected and analyzed. Fig. 11.45 shows an example. The signal on the beam trace is the PKP wave of an underground nuclear explosion at Mururoa Atoll. The onset time and signal amplitude of a weak seismic signal can only be read on the beam. The peak-to-peak amplitude is only about 2 nm with a period around 1 s.

**Fig. 11.45** Detection of the PKP wave of a nuclear explosion at Mururoa Atoll on 27 June 1982 at the Gräfenberg array using the delay-and-sum-method and a very narrowband Butterworth bandpass filter (BP) centered around 1 Hz. The event occurred at an epicentral distance of  $146^\circ$  and the explosion yield was approximately 1 kt TNT.

### 11.3.5 f-k and vespagram analysis

Array-techniques such as f-k and vespagram analysis (Chapter 9) should be applied only to records with coherent waveforms. Vespagram analysis or the velocity spectrum analysis is a method for separating signals propagating with different apparent horizontal velocities. The seismic energy reaching an array from a defined backazimuth with different slownesses is plotted along the time axis. This allows identification of later phases based on their specific slowness values. The best fitting slowness is that for which a considered phase has the largest amplitude in the vespagram. Fig. 11.46 shows the original records from the GRSN (top) and the related vespagram (bottom). More vespagrams are given in Figures 12e–g of DS 11.2.

**Note:** The original vespagram or VESPA process was defined for plotting the observed energy from a specific azimuth for different apparent velocities as isolines versus time (Davies et al., 1971) and not beam traces with maximum amplitudes for maximum energy from a specific azimuth for different apparent velocities (or slowness) as here and in DS 11.2. For “true” vespagrams see Chapter 9, e.g., Fig. 9.30). But we feel that the trace beam presentation with different maximum amplitudes instead of the energy isolines eases the phase identification.

**Fig. 11.46 Top:** Simulated vertical-component WWSSN-LP seismograms from an earthquake in the region of Papua New Guinea. Source data NEIC-QED: 10 May 1999; depth 137 km; mb = 6.5; D = 124° to GRF, BAZ = 51°. The phases Pdif (old Pdif), PKPdf, pPKPdf, PP, pPP, sPP and an unidentified phase X have been marked. **Bottom:** Vespagram of the upper record section. The analysis yields slowness values of 4.5s/° for Pdif, 2.0s/° for PKPdf and pPKPdf, 7.0s/° for PP, and a value that corresponds to the slowness for Pdif for the unknown phase X.

The f-k analysis is used to determine slowness and backazimuth of coherent teleseismic wave groups recorded at an array. Fig. 11.47 shows an example. The epicentral distance must be much larger than the aperture of the recording array. The f-k analysis transforms the combined traces within a current time window (Fig. 11.47a) into the frequency-wavenumber domain. The result in the f-k domain is displayed in a separate window (Fig. 11.47b) with amplitudes (corresponding to wave energy) coded in color. A good result is achieved when there is a single, prominent color in the maximum (yellow in Fig. 11.47b). This maximum denotes slowness and backazimuth of the investigated phase and is helpful for source parameter determination and phase identification. The example was recorded at the GRF-array from an earthquake in East of Severnaya Zemlya. Slowness and backazimuth (BAZ) values are 7.39 s/° and 12.3°, respectively. These values have been used for producing the beam.

**Figs. 11. 47a-b (below)** Illustration of the procedure of frequency-wavenumber (f-k) analysis: a) coherent P-wave signals recorded at the GRF-array stations from an earthquake on 19 April 1997 (the box marks the time window selected for the f-k-analysis); b) energy (coded in colors) in the frequency range 0.39-2.97 Hz as a function of wavenumber k. A good result is achieved because the single, prominent maximum (in yellow) shows the presence of a coherent signal. The estimated slowness and BAZ values are 7.39 s/° and 12.3°, respectively.

**Fig. 11.47a**

Fig. 11.47b

### 11.3.6 Polarization analysis

The task of polarization analysis is the transformation of recorded three component seismograms into the ray-oriented co-ordinate systems. For linearly polarized and single pulse P waves in a lateral homogeneous Earth, this task is simple, at least for signals with a high SNR; the direction of the polarization vector of the P wave clearly determines the orientation of the wave co-ordinate system. However, when propagating through heterogeneous and anisotropic media, the seismic waves have three-dimensional and frequency-dependent particle motions and the measured ray-directions may scatter by ten degrees and more about the great circle path from the epicenter to the station (Figs . 2.7 and 2.8 in Chapter 2). Accordingly, one may also describe the wave polarization by its attributes *rectilinearity*, *planarity* and/or the *largest eigenvalue* (e.g., Wagner and Owens, 1996). If the three main axes of particle motion in space are  $\lambda_1$ ,  $\lambda_2$  and  $\lambda_3$  than the rectilinearity is  $rect = 1 - (\lambda_2 + \lambda_3)/2\lambda_1$  and the planarity  $plane = 1 - 2\lambda_3/(\lambda_1 + \lambda_2)$  (Flinn, 1965). Their values may vary between 1 (ideal linearity or planarity) and 0.

Determination of particle motion is included in most of the analysis software. For identification of wave polarization and investigation of shear-wave splitting, the rotation of the traditional components N, E, and Z into either a ray-oriented co-ordinate systems (L, Q, T) or in the directions R (radial, i.e., towards the epicenter) and T (transverse, i.e., perpendicular to the epicenter direction) is particularly suitable for the identification of secondary later phases. An example for the comprehensive interpretation of such phases in a teleseismic record is given in Fig. 11.48.

**Fig. 11.48** Simulation of three-component WWSSN-LP seismograms of the Volcano Islands earthquake of 28 March 2000, recorded at station RUE in Germany ( $D = 94^\circ$ ,  $h = 119$  km). The horizontal components N and E are rotated into R and T components. The phases P, pP, SP and the beginning of the dispersed surface Rayleigh wave train LR are marked on the vertical-component seismogram, SKS, PS on the radial component (R) and S, SS, SSS and the beginning of the Love waves LQ on the transverse component (T), respectively. Not marked (but clearly recognizable) are the depth phases sS behind S, sSS behind SS, and SSSS+sSSSS in the T component before LQ. The plotted record length is 41min.

## 11.4 Software for routine analysis

### 11.4.1 Brief overview and software library links

There are many different software packages available for automatic and manual processing of earthquake recordings. Some are mainly suited for scientific analysis of the data, others permit the fast routine processing, which includes the generation of reports and maps as needed for the information to the authorities and the public about relevant seismic activity. The companies which sell seismic networks provide commercial software for these tasks. A well-known software of this type is *Antelope* ([www.brtt.com](http://www.brtt.com)). For a briefing Chapter 8, section 8.4.2.2. Other programs were created by university groups or seismological institutions to improve their work such as SHM, SEISAN, SeisComp3 and Earthworm. They were published under free or partially free licencing schemes and applied by other seismologists with so good results that they were later adopted by many observatories and network centers. For more details sections 11.4.2 to 11.4.5. Most of the analysis examples shown in this Chapter have been processed interactively by using the SHM and SEISAN software which belong to the latter type of software. Several software packages combine the fully automatic on-line and seismic data acquisition, archiving, integration, processing and interactive reprocessing such as the commercial SeisComP. Olivieri and Clinton (2012) published a detailed comparison of the features and performance of Earthworm and SeisComp3.

The ORFEUS Software Library (<http://orfeus.knmi.nl/>) presents a comprehensive list and links to available software in seismology, both for routine seismogram analysis and different research tasks. The focus is on shareware, but some relevant commercial sites are also included. Links to the USGS (<http://earthquake.usgs.gov/research/software/>) and the IRIS software libraries (<http://www.iris.edu/manuals/>) are included as well. The latter provides also detailed information about the Seismic Analysis Code (SAC; Goldstein et al, 2003; Goldstein and Snoke, 2005). SAC2000 is used by more than 400 institutions worldwide on a diversity of platforms. Its signal processing capabilities include data inspection, signal correction, and quality control; travel-time analysis and magnitude estimation; spectral analysis and spectrograms, array and three-component analysis. These features are widely used not only in earthquake, explosion and volcanic source studies and the investigation of Earth structure, wave path and site effects but also in the analysis of other geophysical data related to electromagnetic and hydroacoustic phenomena.

Available at the [Orfeus ftp site](#) is also the program *PREPROC* for preprocessing (filtering, restitution, simulation etc.) of seismic traces, seismograph calibration, and fast ray synthetic seismograms for body waves (Authors: Axel Plesinger, Miroslav Zmeskal and [Jan Zednik](#)).

An older, widely used interactive analysis program, *PCEQ*, for IBM compatible PCs, had been written by C. M. Valdés. It was published as Volume 1 of the IASPEI Software Library (Lee, 1995) and works with the location program HYPO71 for local events. Its principal features are: picking P- and S-wave arrivals; filtering the seismogram for better P- and S-wave picks, and computing the spectra of selected seismogram sections. Quite many analysis examples presented in this Manual, e.g., on event location, spectral and polarization analysis, had been processed with the rather comfortable and appealing software *SEIS89* (Baumbach †, 1999) which is, regrettably, no longer maintained because of the death of the author.

Andrey Petrovich Akimov wrote the program WSG (in English AWP: Automated workplace of seismologists). It works in an environment of Windows 95/98/NT and is used at single stations and seismic networks for estimating parameters from local, regional and teleseismic sources. The program converts different seismic data formats such as XDATA, PCC-1, CSS 2.8 and 3.0, DASS, CM6 GSE2 and can import via the TCP/IP protocol data from NRTS and LISS systems (miniSEED). Program and documentation in Russian for version 4.5 are available via [http://www.ceme.gsras.ru/engl/stations/wsg\\_arm.htm](http://www.ceme.gsras.ru/engl/stations/wsg_arm.htm).

Another relevant complementary software, named *Geotool*, has been developed at the CTBTO (Chapter 15) for interactively displaying and processing seismoacoustic data from the International Monitoring /system (IMS). A Software User Tutorial provides a set of exercises that cover the full range of functionality of the software system. It is available via [http://www.ctbto.org/fileadmin/user\\_upload/procurement/2013/Ap\\_D\\_Part1.pdf](http://www.ctbto.org/fileadmin/user_upload/procurement/2013/Ap_D_Part1.pdf), The tutorial covers, amongst others, filter procedures, display and aligning of waveforms, measurement and review of signal arrivals and amplitudes, particle motion analysis and component rotation, waveform analysis (Fourier Transform and spektrograms), f-k and cepstrum analysis, signal correlation, event location, production of bulletins, maps and map overlays.

The wide variety of computer platforms, file formats, and methods to access seismological data often requires considerable effort in preprocessing such data. Although pre-processing work-flows are usually very similar, few software standards exist to accomplish this task. *ObsPy* offers solutions to this problem (section 11.4.6).

## 11.4.2 SHM

The Seismic Handler Motiv, SHM, is a powerful program for analyzing local, regional and teleseismic recordings with station networks or arrays. It has been developed at the BGR (Federal Institute for Geosciences and Natural Resources) originally for the analysis of data from the Gräfenberg (GRF) array and the German Regional Seismic Network (GRSN) (author: Klaus Stammler; recent developments by Marcus Walther). Program and descriptions are available via <http://www.seismic-handler.org>. A screen display of SHM is shown in Fig. 11.49.

**Fig. 11.49** Screen display of the seismic analysis program SHM. Different windows display a number of station recordings (large window), a zoomed single-station window, two seismogram and source parameter windows (left side) and an output window for the results of

Main features of SHM are:

- application of array procedures to a set of stations (slowness- and backazimuth determination by means of beamforming and f-k analysis);
- location algorithms (teleseismic locations using travel-time tables and empirical correction vectors, local and regional locations via external programs, e.g., LocSAT).

The basic program has some (more or less) standardized options, e.g.:

- manual and automatic phase picking (Figs. 11.5 and 11.6);
- trace filtering with simulation and bandpass filters (Figs. 11.37 to 11.40);
- determination of amplitudes, periods and magnitudes (Fig. 11.4);
- display of theoretical travel times on the traces (Fig. 11.48 and 11.52).

Furthermore, the following tasks are implemented:

- rotation of horizontal components (Figs. 11.17, 11.18 and 11.48);
- particle motion diagrams (Fig. 2.7);
- trace amplitude spectrum (Fig. 11.60);
- vespagram trace display (Fig. 11.46);
- determination of signal/noise ratio (Fig. 11.60); and
- trace editing functions.

In 2012 an optional plugin for the magnitude determinations following the IASPEI standards has been implemented, as an alternative to the slightly differing traditional magnitude routines and filter parameters of the Gräfenberg observatory (mb, MS, ml). All resulting parameters are stored in an easily readable and extendable text file format. Different waveform data formats are supported, however the preferred data format is continuous MiniSEED. SHM is supported on a number of Linux distributions (see web page).

### 11.4.3 SEISAN

Another widely used seismic analysis system is SEISAN developed at University of Bergen, Norway (Ottemöller, Voss, and Havskov, J. (Eds.) (2013). It contains a complete set of programs and a simple database for analyzing digital recordings. SEISAN can be used, amongst other things, for phase picking, spectral analysis, azimuth determination, and plotting seismograms. SEISAN is supported by DOS, Windows95, SunOS, Solaris and Linux and contains conversion programs for the most common data formats. The program, together with a detailed Manual, is available via <http://www.ifjf.uib.no/seismo/software/seisan/seisan.html> and can also be downloaded from the Manual front page via the link *Download programs and files*. IS 11.6 gives examples of record and parameter presentation, the picking of phase onset times, amplitudes and periods, event location and magnitude determination in the local, regional and teleseismic distance range and the determination of source mechanisms by using either first motion polarities or S/P amplitude ratios. Since its version 8.3 SEISAN is so far the only widely used interactive analysis software (besides the NEIC Hydra software) that has implemented as default the IASPEI recommended filters for determining the standard magnitudes. On the records, where the respective amplitudes and periods are measured, the cursors are annotated with the related unique standard amplitude phase names (Table 4 in IS 3.3 and Fig. 11.50). However, as of now (October 2013), neither SEISAN nor any other currently operating analysis software, with the exception of the NEIC Hydra system, presents the standard magnitudes, with the exception of mb and ML, also in their standard nomenclature (e.g., mB\_BB, Ms\_20, Ms\_BB). Therefore, with its resolution No. 1 of 2013 (Fig. 11.36) IASPEI encourages developers of waveform processing programs to incorporate these standards into their software and the station and network operators as well as data centers to adopt these magnitude and amplitude standards in their day to day operations.

**Fig. 11.50** Compiled from SEISAN analysis example 3 in IS 11.6. **1) Uppermost trace:** Velocity broadband record at station ARU ( $D = 26.2^\circ$ ) of the 24 May 2012 Mw6.2 Mohns Ridge earthquake, offshore northern Norway. **Lower trace:** broadband velocity surface wave window with the marked position for  $M_s$ \_BB amplitude measurement, annotated with the standard amplitude phase name  $IVM_s\_BB$ . **2) to 4)** Filtered traces for  $M_s$ \_20,  $mB\_BB$  and  $mb$  amplitude measurements according to IASPEI standards with marked positions annotated with the respective standard amplitude phase names  $IAM_s\_20$ ,  $IVmB\_BB$  and  $IAmb$ . I stands for IASPEI standard, A for displacement amplitude and V for velocity amplitude.

Since the beginning of the 1990s, SEISAN was installed in many developing countries in Central and South America, the Caribbean, Asia and Africa by the seismological institutions University of Bergen and NORSAR within Norwegian technical assistance projects on seismic hazard and risk mitigation. The package served very well the needs of the seismological observatories of these countries, was improved and developed taking into account the variable environments and user inputs. The package unites routine seismic processing, reporting, and programs for scientific analysis, for crustal structure, seismic hazard estimation and other topics. The program had always a companion program named SEISLOG for data acquisition and event detection. A new module RTQUAKE is in development which includes also automatic event location. A combination of RTQUAKE and SEISAN could be a good alternative for seismologists at small networks who fear the difficulties to install Earthworm or SeisComP which have a rather steep learning curve.

#### 11.4.4 SeisComP3

SeisComP (Seismological Communication Processor; Hanka et al., 2000 and 2010; <http://www.seiscomp3.org>) is the most commonly used software in Europe within the scope of real-time earthquake monitoring and increasingly also on a global scale with meanwhile about 300 installations/licenses granted world-wide. It had originally been developed in conjunction with the GEOFON network (Hanka and Kind, 1994; see also Chapter 8, Fig. 8.5) and the GEOFON earthquake information system operated at GFZ (German Research Centre for Geosciences in Potsdam) (see <http://geofon.gfz-potsdam.de/>). All stations in the global GEOFON network send their data in real time to the GFZ.

A major breakthrough has been the development of the SeedLink protocol for data acquisition and transfer (Hanka et al., 2000) as part of the GEOFON's SeisComP concept. It permits the connection of digitizers and data loggers from all major manufacturers and all major acquisition systems, the conversion of the native data formats to MiniSEED (for formats Chapter 10) and the uniform transmission, acquisition and archival of heterogeneous network data (Hanka et al., 2010). Automatic real-time data processing became part of SeisComP in 2003. The early GFZ prototype earthquake monitoring system was upgraded with SeisComP3 (for short SC3) which forms a powerful system able to issue within a few minutes automatic but nevertheless rather reliable global and regional earthquake parameter information. Moreover, SC3 allows later interactive refinement and distribution of revised solutions. This system provides now the backbone for the German Indonesian Tsunami Early Warning System (GITEWS; <http://www.gitews.org/index.php?id=6>), for other tsunami warning centers in the Indian Ocean and the NEAMTWS (Northeastern Atlantic and Mediterranean Tsunami Warning System) area as well as for the GEOFON Extended Virtual Network (GEVN) which presently comprises more than 900 stations world-wide (Hanka et al., 2010).

Besides reliable near real-time automatic data processing SC3 allows very rapid visualization of the results, quick graphical review, and interaction of seismic experts in the warning centers at any time in order to improve the automatic results. This was a precondition under the GITEWS time constraints to issue tsunami warnings already within 5 min after origin time. According to Hanka et al. (2010) the basic automatic system of SC3 consists of modules for:

- quality control
- picking
- event location

- amplitude and magnitude calculation
- waveform quality assessment and
- event and station parameter management.

The interactive part of the system provides according to Hanka et al. (2010):

- graphical user interfaces for visualizing in a map the overall situation regarding earthquake location and station status (Fig. 11.51)
- real-time trace and event summary display
- toolkits for analyzing the earthquake epicenter, source depth and magnitude
- manual picker optimized for rapid verification of pre-calculated picks from strong earthquakes
- automatic loading of newly acquired real-time data with picks associated to the ongoing event
- automatic amplitude scaling and trace alignment
- conventional off-line event analysis, also of small and moderate earthquakes that have not been processed by the automatic system.

The latter point allows for more detailed and accurate seismic phase and magnitude measurements for the final station and/or network parameter bulletins and thus also for making valuable contributions to final regional and global seismological parameter bulletins, e.g., of the EMSC and the ISC, in agreement with IASPEI recommended measurement standards. Making full use of the off-line data processing and analysis potential offered by SC3 reduces procedure dependent data scatter and systematic biases. This assures best representativeness, long-term compatibility and accuracy of its final data products also on a global scale, thus improving the usefulness of international parameter data bases for earthquake statistics, hazard assessment and other research tasks.

Although SC3 measures in its automatic mode, besides several other magnitudes, in principle already two of the four IASPEI recommended teleseismic standard magnitudes, namely mb and mB\_BB, the stringent time limit set for early warning applications requires to measure mb already within the first 30 s and mB within the first 60 s of the event record traces. For the greatest or very slow strong earthquakes this means, however, that the largest amplitude in the P-wave train may still be missed by such a pre-set measurement time window, more frequently for mb but occasionally also for mB (see, e.g., Figs. 3.6, 3.13, 3.46, 3.62 and 3.65 in Chapter 3). Then these two body-wave magnitudes but also the Mw proxy estimate Mw(mB) (see Bormann and Saul, 2008) may be underestimated, up to about 0.3 magnitude units (m.u.) This can be corrected easily by later off-line analysis, when the whole wave train is available. Then also the very important complementary broadband surface-wave magnitude standard Ms\_BB (Chapter 3, section 3.2.5), can be measured without any restrictions set by the rapid automatic processing mode when applied to large global sets of waveform data for early warning purposes. For smaller networks, however, it is said to be practicable already even in the automatic mode.

Originally developed for tsunami early warning, SC3 evolved also to be a very powerful system for local earthquake monitoring including off-line analysis, providing typically needed functionality as customizing and applying filters to the records, project theoretical phase onset times on the records, allow axes rotations to ease phase detection and identification and provide a first motion analysis to determine source mechanisms.

**Fig. 11.51** SeisComP3 screenshots of an authentic playback from the Tohoku earthquake on March 11, 2011. **Left** side: Screenshot from the SC3 module to review/revise hypocenter solutions; **right side** shows the event summary view (Figure by courtesy of B. Weber).

## 11.4.5 Earthworm

Earthworm is a non-commercial seismological software package (Johnson et al., 1995; <http://folkworm.ceri.memphis.edu/ew-doc/> and <http://www.earthwormcentral.org/>). On its web page it is described as follows:

“Earthworm is an open architecture, open source public software for data acquisition, processing, archival and distribution. It was originally developed by the United States Geological Survey. Earthworm binaries and source files are freely available to everyone. Development and maintenance are now carried out by the Earthworm User Community, [ISTI](http://www.isti.com/) (Instrumental Software Technologies, Inc., New York, USA) and [CERI](http://www.ceri.edu/) (Center for Earthquake Research and Information, University of Memphis, USA).”

The software is written in C and can be compiled for Windows, Linux, Solaris and Mac OS X operating systems. Precompiled binaries can be downloaded from the Earthworm websites. Earthworm seismic data acquisition and processing software can be used for single stations as well as local, regional and global seismic networks. The development of the package started in 1993. Nowadays, over 150 institutions have registered installations of Earthworm. Many more “Earthworms” run on the office computers or Laptops of seismologists, geophysicists, and hobbyists without formal registration as the software is completely free. In addition to seismology, Earthworm's data acquisition and management capabilities are used for other waveform data, including Infra-sound, Geomagnetic, and Atmospheric measurements.

Earthworm is very structured and consists of around 130 modules which the user can configure according to his needs and combine them for executing a specified task. This task can be so simple as to acquire the data of a single component and write its data to disk. The script which controls the execution would contain only a few lines and an experienced user would edit it in some minutes. The task can also be rather complicated as to acquire, in real time, the data of a network of several hundred stations, perform band pass filtering and phase picking for all the traces, event definition, automatic localization and magnitude determination. To control such a demanding task necessitates, however, a rather large script which might require many weeks or months of development and testing to get it working properly. Simpler Earthworm configurations can run on very cheap and small computers such as the Raspberry Pi. For a small or medium seismic network a low cost PC with two cores could be sufficient. Larger networks of several hundred stations require more powerful computers. Different tasks could even been distributed to several servers in the seismic data center.

There are around 30 data acquisition modules suited for many of the A-D-cards and digital seismographs on the market, even for some cheap A-D-cards used mainly by hobbyists. Earthworm systems can communicate with each other as with other data acquisition and processing systems (e.g. SeisComP) by using special modules. For instance, an Earthworm installed on a simple computer with an A-D card could acquire data at a seismic station and transmit them in real time to another Earthworm or SeisComP which is running in a server of the seismic data center and performs the automatic earthquake detection and processing. Earthworm has also modules for sending out email messages triggered by seismic event detection but Earthworm lacks sophisticated visualization tools for seismogram.

“Glowworm” is a special suite of Earthworm modules that has been developed at the USGS in the late 1990s. It contains data archiving and processing methods and visualization tools typical for volcano monitoring. Nowadays, Glowworm seems to be outdated as several of its modules were not adapted to structural changes of the main stream of Earthworm. Nevertheless, it is still in use in many volcano observatories. The most important processing modules of original Glowworm, e.g. for the continuous calculation of RSAM (*Real-time Seismic-Amplitude Measurement*, which represents the overall signal size over periods of 10 minutes) and SSAM (*Seismic Spectral-Amplitude Measurement*, which shows the relative signal size in different frequency bands) were ported to the standard Earthworm.

Standard Earthworm is dedicated only to automatic data acquisition and routine processing. Therefore it has no own interactive processing modules. But it contains modules which permit the generation of event files in data formats needed by other seismological data processing programs, for instance SEISAN or SAC. These packages can then be used for interactive routine processing or for scientific research. A widely used combination at seismological observatories with smaller networks and lack of personnel experienced in computing and programming is to use Earthworm for data acquisition, event detection and generation of event files; and SEISAN for the interactive routine processing of the events. This avoids the automatic location and magnitude determination which is not easy to configure. Based on Earthworm the Alaska Tsunami Warning Center (ATWC) developed the *Early Bird* package (Luckett et al., 2008) for the detection, automatic location and magnitude determination of local, regional and teleseismic events, especially for tsunami warning. It contains also modules for seismogram visualization and interactive processing, phase picking and generation of epicenter maps.

## 11.4.6 ObsPy

*ObsPy* is an open-source project (Beyreuther et al. 2010; Megies et al., 2011) aimed at facilitating rapid application developments for seismology. It provides a toolbox using *Python* language (<http://www.python.org/> and <http://en.wikipedia.org/wiki/Python>) and simplifies the usage of Python programming for seismologists. It provides parsers for common file formats, clients to access data centers and seismological signal processing routines that allow the manipulation of seismological time series. Good starters are [ObsPy Gallery](#) and Tutorial (<http://docs.obspy.org/index.html>). *ObsPy* is currently [running and tested](#) on Linux, Windows XP/Vista/7/8 and Mac OS X.

In *ObsPy* the following essential seismological processing routines are implemented and ready to use:

- reading and writing data only SEED/MiniSEED and Dataless SEED ([http://www.iris.edu/manuals/SEEDManual\\_V2.4.pdf](http://www.iris.edu/manuals/SEEDManual_V2.4.pdf));
- XML-SEED (Tsuboi et al. 2004);
- GSE2 ([http://www.seismo.ethz.ch/autodrm/downloads/provisional\\_GSE2.1.pdf](http://www.seismo.ethz.ch/autodrm/downloads/provisional_GSE2.1.pdf)) and
- SAC (<http://www.iris.edu/manuals/sac/manual.html>), as well as filtering, instrument simulation, triggering, and plotting.
- Modules to read SEISAN data files (Havskov and Ottemöller 1999) and to retrieve data with the IRIS/FISSURES data handling interface (DHI) protocol (Malone 1997);
- Support to retrieve data from ArcLink (a distributed data request protocol for accessing archived waveform data, see Hanka and Kind 1994) or a SeisHub database (Barsch 2009).

While Python gives the user all the features of a full-fledged programming language including a large collection of scientific open-source modules, *ObsPy* extends Python by providing direct access to the actual time series, thus allowing the use of powerful numerical array-programming modules like NumPy (<http://numpy.scipy.org>) or SciPy (<http://scipy.org>) and the visualization of the results. This is an advantage over SAC, SEISAN, and SeismicHandler which do not provide methods for general numerical array manipulation.

## 11.5 Examples of seismogram analysis

### 11.5.1 Introductory remarks

The character of a seismogram depends on the source mechanism and size, the source depth, the signal-to-noise ratio (SNR) and whether the epicenter of the source is at local, regional or teleseismic distances. Many seismic phases of different origin and character may occur in these different ranges. For explanations of their phase names and origin see IS 2.1. In the following we deliberately show mostly records with good SNR because we wish to illustrate what types of seismic phases, also relatively weak ones with respect to the strongest phases, may occur at which distances and what their basic features such as relative travel-time, period, amplitude and polarity are with respect to other phases. However, most seismic events are relatively weak and therefore the SNR is low and most signal phases are buried in the noise, especially in broadband records. Then filter procedures have to be applied in order to improve the SNR. But what types of filters are suitable depends on the frequency, wave number and polarization properties of the signal and of the noise. These problems, including

those of bandwidth-dependent waveform distortion due to filtering, are outlined in detail in Chapter 4. There also many examples are presented on SNR-improvement by applying different types of filters and their pros and cons are discussed. For array-specific methods of SNR improvement see also Chapter 9 and in the Data Sheets DS 11.1-11.3 more examples are given that show the different record appearance depending on the applied filter and time resolution. There are no straightforward standardized receipts for optimal filtering. Which filter procedure and parameters are best suited also depends on which parameters (such as onset time, amplitude, period, slowness or polarization) have to be determined best in which frequency range and of what type of seismic phase. Only rich own interactive and task-dependent experience can help to develop the proper “feeling” for it. Who only uses and relies on some basic default parameter settings of automated procedures will never get a deeper understanding of it and learn to discriminate between real signal improvements, distortions or even filter-induced artifacts.

Seismograms of small local earthquakes are characterized by short duration of the record from a few seconds to 1-2 minutes, higher frequencies, and a characteristic shape of the wave envelope, usually an exponential decay of amplitudes after the amplitude maximum, termed “coda” (Figure 1b in DS 11.1 and Figure 2 in EX 11.1). However, records of large earthquakes with longer rupture duration and thus radiating dominantly longer periods may look differently in the local distance range. At teleseismic distances records show generally lower frequencies (because high-frequency energy has already been reduced by anelastic attenuation and scattering), and much longer duration from say fifteen minutes to several hours (e.g., Figs. 1.6, 2.20, 2.21 and 11.52).

**Fig. 11.52** Example of 3-component broadband velocity seismograms of a teleseismic  $M_w = 7.7$  earthquake in El Salvador recorded at station MOX, Germany ( $D = 86.5^\circ$ ).

Records of regional events at distances of several hundred kilometers have intermediate features, and are - as local events - characterized by still high frequency content and only a few distinct phase onsets with much signal-generated noise in between due to scattering at crustal heterogeneities. This hardly allows to recognize and pick for sure the onsets of weaker but theoretically expected phases such as  $P_b$ ,  $S_b$ , and  $S_n$  (Figs. 11.53 and 11.54 in section 11.5.1).

The various wave groups above the noise level, arriving at a station over different paths, are called seismic phases. They have to be recognized, identified and their parameters determined (onset time, amplitude, period, polarization, etc.). Phase symbols should be assigned according to the IASPEI recommended standard nomenclature of seismic phases. For phase names, their definition and ray paths see IS 2.1. Types and characteristics of seismic phases vary with distance, depending also on the source type and depth. These characteristics will be discussed in more detail in the following sections.

There is no unique standard definition yet for the distance ranges termed “near” or “local” and “regional” (near to far regional), or “distant” (“teleseismic”; sometimes subdivided into “distant” and “very distant”). Regional variations of crustal and upper-mantle structure make it impossible to define a single distance at which propagation of local or regional phases stops and only teleseismic phases will be observed. In the following we consider a source as local if the direct crustal phases Pg and Sg arrive as first P- and S-wave onsets, respectively. In contrast, the phases Pn and Sn, which have their “bottoming” (or starting) point in the uppermost mantle, are the first arriving P and S waves in the regional distance range. However, as discussed in Chapter 2, section 2.6.1 and shown in Fig. 2.47, the distance at which Pn takes over as first arrival depends on the crustal thickness, average wave speed and the dip of the crustal base. The “cross-over” distance  $x_{co}$  between Pn and Pg is - according to Eq. (6) in IS 11.1 for shallow (near surface) sources - roughly  $x_{co} \approx 5 \times z_m$  where  $z_m$  is the Moho depth. Note, however, that as focal depth increases within the crust,  $x_{co}$  decreases, down to about  $3 \times z_m$ . Accordingly, the local distance range may vary from region to regions and range between about 100 km and 250 km. The CTBTO Technical Instructions (see IDC Documentation, 1998) considers epicentral distances between  $0^\circ$  to  $2^\circ$ , where Pg appears as the primary phase, as local distance range.

The Willmore (1979) Manual defines as near earthquakes those which are observed up to about 1000 km (or  $10^\circ$ ) of the epicenter, and P and S phases observed beyond  $10^\circ$  as usually being teleseismic phases. However, regional phases such as Pn, Sn and Lg, will generally propagate further in stable continental regions than in tectonic or oceanic regions. According to the Earth model IASP91, Pn may be the first arrival up to  $18^\circ$ . The rules published in the IDC Documentation (1998) allow a transitional region between  $17^\circ$  and  $20^\circ$  in which phases may be identified as either regional or teleseismic, depending on the frequency content and other waveform characteristics. Accordingly, one might roughly define seismic sources as local, regional and teleseismic if their epicenters are less than  $2^\circ$ , between  $2^\circ$  and  $20^\circ$ , or more than  $20^\circ$  away from the station. Sometimes, the regional range is further subdivided into  $2^\circ$ - $6^\circ$ , where also the phase Rg may be well developed (Fig. 11.23), and  $6^\circ$ - $20^\circ$  where only Sn and Lg are strong secondary phases.

On the other hand, the calibration curve for the local magnitude  $M_L$  according to Richter (1935) has originally been given for distances up to 600 km and has been extended now for some regions far beyond (up to 1500 km, Table 2 in DS 3.1) making  $M_L$  an even far regional magnitude. On the other hand, the new IASPEI standards for teleseismic magnitudes  $m_b$  and  $M_s(20)$  are measured between  $20^\circ$  and  $100^\circ$ , respectively  $20^\circ$  and  $160^\circ$ , whereas the broadband surface-wave magnitude  $M_s(BB)$ , measured between  $2^\circ$  and  $160^\circ$ , is in fact both a regional and a teleseismic magnitude.

At distances beyond  $15^\circ$  Pn and Sn amplitudes become too small (except in some shield regions). The first arriving P and S phases have then already taken travel paths through deeper parts of the upper mantle, thus being affected by the pronounced velocity increases at the

bottom of the upper mantle (410 km discontinuity) and at the bottom of the transition zone to the lower mantle (660 km discontinuity) (Chapter 2, Figs. 2.77 and 2.79). This gives rise to the development of two triplications of the P- and S-wave travel-time curves with prograde and retrograde branches, the second one reaching up to about  $28^\circ$  epicentral distance. In some distance ranges the related P and S onsets follow closely to each other (Figs. 2.32 and 2.76), thus forming rather long and complex waveforms (Fig. 11.53). The largest amplitudes occur in the range of the left-side cusp of the 660 km discontinuity triplication (P660P) between about  $18^\circ$  and  $21^\circ$  (termed “ $20^\circ$ -discontinuity”; see also the amplitude-distance curves in Fig. 11.10) but with weaker P-wave first arrivals some 5 to 10 s earlier. Accordingly, small differences in epicentral distance can lead to large differences in the amplitude of the body-wave groups in seismic records (see also Figure 2b in DS 11.2).

SK1: 1993.232.05.r7

**Fig. 11.53** 3-component records in the distance range between  $7.9^\circ$  and  $21.1^\circ$  by a regional network of portable broadband instruments deployed in Queensland, Australia (seismometers CMG3ESP; unfiltered velocity response). The event occurred in Papua New Guinea at 15 km depth. The predicted phase arrival times for the AK135 model are depicted. Primary, depth and other secondary arrivals (such as PnPn in the P-wave group and SbSb as well as SgSg in the S-wave group) superpose to complex wavelets. Also note that several of the theoretically expected phases have such weak energy that they cannot be recognized on the records at the marked predicted arrival times above the noise level or the signal level of other phases (e.g., PcP) (courtesy of B. Kennett).

These complications and different pros and cons for various definitions notwithstanding we present, slightly different from NMSOP-1 and DS 11.2, in the following the examples from near to regional sources up to about  $20^\circ$ , in the teleseismic range between about  $20^\circ$  and  $100^\circ$ , and in the far teleseismic “core shadow” range beyond  $100^\circ$ ,

## 11.5.2 Seismograms from near and regional sources ( $0^\circ < D < \approx 20^\circ$ )

Seismograms recorded in this distance range are dominated by P and S waves that have traveled along different paths through the crust and the upper mantle of the Earth. They are identified by special symbols for “crustal phases” (see IS 2.1). Pg and Sg, for example, travel directly from a source in the upper or middle crust to the station whereas the phases PmP and SmS have been reflected from, and the phases Pn and Sn critically refracted along or “dived beneath” the Moho discontinuity (Fig. 11.53). Empirical travel-time curves are given in Exercise EX 11.1 (Figure 4) and a synthetic record section of these phases in Fig. 2.82. In some continental regions, phases are observed which have been critically refracted from a mid-crustal discontinuity or have their turning point in the lower crust. They are termed Pb (or P\*) for P waves and Sb (or S\*), for S waves, respectively. For shallow sources, crustal “channel-waves” Lg (for definition see IS 2.1) and surface waves Rg are observed after Sg-waves. Rg is a short-period Rayleigh wave ( $T \approx 2$  s) which travels in the upper crust and is usually well developed in records out to about 300 km of near-surface sources such as quarry blasts or mining induced events and thus suitable for discriminating such events from local tectonic earthquakes (Figs. 11.23a-d).

**Fig. 11.54** Ray traces of the main crustal phases that are observed in the near (local and regional) distance range from seismic sources in a simple two-layer model of the Earth's crust. The phase names are according to the new IASPEI nomenclature (see IS 2.1) (Figure courtesy of J. Schweitzer, 2002)

Usually, Sg and SmS (the supercritical reflection, which often follows Sg closely at distances beyond the critical point; Fig. 2.43) are the strongest body wave onsets in records of near seismic events whereas Pg and PmP (beyond the critical point) have the largest amplitudes in the early part of the seismograms, at least up to 200 – 400 km. Note that for sub-crustal earthquakes no reflected or critically refracted crustal phases exist. However, according to the new IASPEI nomenclature, P and S waves from sub-crustal earthquakes with rays traveling from there either directly or via a turning point in the uppermost mantle back to the surface are still termed Pn and Sn (Fig. 11.54, lower left). At larger distances such rays arrive at the surface with apparent “sub-Moho” P and S velocities (see below).

Typical propagation velocities of Pg and Sg in continental areas are 5.5-6.2 km/s and 3.2-3.7 km/s, respectively. Note, that Pg and Sg are direct waves only to about 2° to 3°. At larger distances the Pg-wave group may be formed by superposition of multiple P-wave reverberations inside the whole crust (with an average group velocity around 5.8 km/s) and the Sg-wave group by superposition of S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust. According to the new IASPEI phase nomenclature the definitions given for Lg waves and Sg at larger distances are identical, with the addition that the maximum energy of an Lg crustal “channel” wave travels with a group velocity around 3.5 km/s. According to the definition of the IASPEI mb\_Lg standard magnitude (see IS 3.3) the amplitude of Lg is measured as the “...*third largest amplitude in the time window corresponding to group velocities of 3.6 to 3.2 km/s, in the period (T) range 0.7 s to 1.3 s*”.

In routine analysis, usually only the first onsets of these wave groups are picked without noting the change in character at larger distances. According to the Technical Instructions of the IDC Documentation (1998), stations of the CTBTO International Monitoring System (IMS) generally tend to name the strongest transverse arrival Lg and not Sg. A reliable discrimination is still a subject of research and not yet one of routine analysis and data reporting. Therefore, no simple and unique criteria for discrimination, which also depend on source type and propagation path, can be given here. They may be added to this Manual at a later time.

Lg waves may travel in continental shield regions over large distances (Fig. 2.15), even beyond 20° whereas Rg waves, which show clear dispersion and longer periods than Lg (Fig. 11.23a and b), are more strongly attenuated and generally not observed beyond 6°. The apparent velocities of Pn and Sn are controlled by the P- and S-wave velocities in the upper mantle immediately below the Moho and typically range between 7.5 - 8.3 km/s and 4.4 - 4.9 km/s, respectively.

**Note:** Seismograms from local and regional seismic sources are strongly influenced by the local crustal structure which differs from region to region and even between local stations. This may give rise to the appearance of other onsets (which may be strong) between the mentioned main crustal phases. These “unexpected” phases cannot simply be explained as direct or refracted/reflected waves radiated from a near-surface source in a single or two-layer crustal model. Some of these phases may relate to converted waves and/or depth phases such as sPmP (e.g., Bock et al., 1996). Also, at larger distances, up to about 30°, multiples such as PgPg, PbPb, PnPn, PmPPmP etc. and their related S phases, are expected to follow each other closely within the P and S-wave group according to the AK135 travel-time model (Fig. 11.53).

However, usually these details cannot be handled in routine data analysis and epicenter location and require specialized study. For routine purposes, as a first approximation, the IASP91 or AK135 global models (see DS 2.1) can be used for the analysis and location of near events based on the main crustal phases. However, one should be aware that crustal structure and velocities may differ significantly from region to region. Therefore, the event location can be significantly improved when local travel-time curves or crustal models are available (e.g., IS 11.1, Figures 11 and 12).

Fig. 11.55 shows seismograms of a shallow local earthquake from the Vogtland/NW Bohemia region in Central Europe, recorded at seven GRSN stations in the epicentral distance

range 10 km (WERN) to 180 km (GEC2). Stations up to  $D = 110$  km (BRG) show only the direct crustal phases Pg, Sg, except GRFO, which in addition shows PmP. At GEC2 Pn arrives ahead of Pg with significantly smaller amplitude. The onset times of phases Pg, Sg and Pn were used to locate the epicenter of this event with a precision of about 2 km. If more stations close to the epicenter are included (e.g., Fig. 11.56;  $D = 6 - 30$  km), the precision of the hypocenter location may be in the order of a few hundred meters.

**Fig. 11.55** Filtered short-period vertical component seismograms (4<sup>th</sup> order Butterworth high-pass filter,  $f = 1$  Hz) from a local earthquake in the Vogtland region, 04 Sept. 2000 ( $50.27^\circ\text{N}$ ,  $12.42^\circ\text{E}$ ;  $h = 8$  km,  $M_l = 3.3$ ). Sampling rates at the stations differ: 80 Hz for MOX, WET, CLL, and BRG, 100 Hz for WERN and 20 Hz for GRFO and GEC2. Traces are sorted according to epicentral distance (from 10 to 180 km). The local phases have been marked (Pg and Sg at all stations, PmP at GRFO and Pn at the most distant station GEC2 ( $D = 180$  km)).

**Fig. 11.56** Short-period recordings from stations of the local network of the Czech Academy of Sciences in Prague from a small ( $M_l = 3.3$ ) local earthquake in the German/Czech border region on June 1, 1997. The epicentral distance range is 6 km and 30 km. Such local networks allow hypocenters to be located to better than a few hundred meters.

From these figures and the animation file 1 in IS 11.3 the following conclusions can be drawn:

- at some stations the arrival times are in good agreement with the times predicted from an average crustal model for the considered region, at other stations they are not. This implies lateral and/or distance-dependent variations in crustal velocities;
- the amplitude ratio  $P_g/S_g$  varies strongly with azimuth because of the different radiation patterns for P and S waves. This can be used to derive the fault-plane solution of the earthquake (Figs. 3.100 - 3.103 in section 3.4.1 of Chapter 3).

Fig. 11.57 shows recordings from an earthquake in the Netherlands ( $M_l = 4.0$ ) in the distance range 112 km to 600 km, and Fig. 11.58 those from a mining-induced earthquake in France ( $M_l = 3.7$ ) in the range 80 km to 500 km. These records again show obvious variations in the relative amplitudes of  $P_n$ ,  $P_g$  and  $S_g$ . The relative amplitudes depend on both distance and azimuth of the stations relative to the radiation pattern of the source, and particularly with respect to the differences in take-off angles of the rays for the direct and the critically refracted waves (Fig. 11.54). The source depth with respect to the major crustal discontinuities may also influence the relative amplitude ratio between these various phases.

As in Figs. 11.23a and b, also the record of station WLF in Fig. 11.58 of this shallow mining induced event shows well developed longer-period  $R_g$  waves that follow  $S_g$ .  $R_g$  is usually not present in records of tectonic earthquakes (Figs. 11.55-11.57).

For near-surface sources and distances smaller than about 400 km,  $P_n$  is usually much smaller than  $P_g$  (see also Fig. 11.34 and Figures 3a and 3c in Datasheet 11.1). But for larger distances the relative amplitudes of  $P_n$  and  $S_n$  may grow so that these phases may even become the dominating first arriving the P and S waves (Fig. 2.17 and the uppermost traces in Figs. 11.57 and 11.58). This is not only because of the stronger attenuation of the direct waves that travel mostly through the uppermost heterogeneous crust, but also because P and S near the critical angle of refraction at the Moho form so-called “diving” phases which are not critically refracted into the Moho but rather travel within the uppermost mantle with sub-Moho velocity. Such diving phases have much larger amplitudes than the ones to be expected by theory for critically refracted inhomogeneous waves. The sub“diving”  $P_n$  and  $S_n$  at distance beyond 600-800 km becoming the dominating first arriving P and S onsets, usually have longer periods than  $P_n$  and  $S_n$  at shorter distances.

**Fig. 11.57** Vertical-component short-period filtered broadband seismograms (4<sup>th</sup> order Butterworth high-pass filter,  $f = 0.7$  Hz; normalized amplitudes) from a local earthquake at Kerkrade, Netherlands, recorded at 15 GRSN, GRF, GERES and GEOFON stations.  $M_l = 4.0$ ; epicentral distances between 112 km (BUG) and 600 km (GEC2). The time difference  $S_n$ - $P_n$  of 60 s in the GEC2 records yields also with the “rule of thumb” in Eq. (1.2) the calculated epicentral distance for this station. Note the variability of waveforms and relative phase amplitudes of local/regional earthquakes in network recordings in different azimuths and epicentral distances. The suitability of filters for determination of local phase onsets has to be tested. Local magnitudes are measured on a Wood-Anderson record simulation.

**Fig. 11.58** Vertical-component short-period filtered BB seismograms (4<sup>th</sup> order Butterworth high-pass filter,  $f = 0.7$  Hz, normalized amplitudes) from a local mining-induced earthquake at the French-German border recorded at 11 GRSN, GERES and GEOFON stations ( $M_l = 3.7$ ; D between 80 km (WLF) and 501 km (GEC2)). Note the well developed more long-period and dispersive  $R_g$  group following  $S_g$  in the record of WLF. Usually one does not find this phase in records of deeper tectonic earthquakes (e.g., Figs. 11.55-11.57).

But Fig. 11.59 shows the great variability in the appearance of waveforms and relative amplitudes in near-earthquake recordings, which often deviate from such average rules. Even seismic records at the same station from two different sources at nearly the same distance and with similar azimuth may look very different. This may be because the waves from the two earthquakes travel along slightly different paths through the highly heterogeneous Alpine mountain range. However, the fault-plane orientation and related energy radiation with respect to the different take-off angle of Pn and Pg may also have been different for these two earthquakes.

**Fig. 11.59** Comparison of Z-component short-period filtered records at station MOX, Germany, of two earthquakes in Northern Italy (trace 1: 28 May 1998; trace 2: 24 Oct. 1994) at about the same epicentral distance ( $D = 505$  km and  $506$  km, respectively) and with only slightly different backazimuth ( $BAZ = 171^\circ$  and  $189^\circ$ , respectively). Note the very different relative amplitudes between Pn and Pg, due to either crustal heterogeneities along the ray paths or differences in rupture orientation with respect to the different take-off angles of Pn and Pg rays.

The recognition and differentiation of the various crustal phases and the precision of onset-time picking can be significantly improved by stretching the time scale in digital records (compare, e.g., Figures 3a and 3c in DS 11.1). But local and regional earthquakes do not only appear in short-period recordings. Stronger near events with magnitudes above 4 usually generate already strong long-period waves (e.g., Figs. 11.11 and 11.13). In BB records of shallow earthquakes Pn and Sn will then be followed by well-developed surface-wave trains of even much larger amplitudes. Figure 6a in DS 11.1 shows a typical 3-component BB-velocity record at station GRA1, Germany ( $D = 10.3^\circ$ ) of such an earthquake in Italy. Figure 6c shows the respective BB records at 10 stations of the GRSN ( $D = 8^\circ - 12^\circ$ ). Pg and Sg are no longer recognizable.

With the exception of the P- and S-wave triplications and thus complicated and elongated P- and S-wave groups at distances beyond  $15^\circ$  the records in the far regional range look rather simple. Usually, only P, S, and surface waves are clearly developed (Fig. 11.53 and Figures 2b and 4c in DS 11.2). The surface waves of shallow earthquakes are strong, clearly separated from the S waves and very useful for surface wave magnitude estimation, with  $M_s(BB)$  even down into the near regional range. In the case of deep earthquakes and thus negligible surface waves the the core reflection PcP may sometimes also be observed in the far regional distance range ( $6^\circ$ - $20^\circ$ +) in short-period seismograms of stronger events ( $M_l > 4$ ). PcP, which gives a good control of source depth, can be identified in array recordings because of its very small slowness (e.g., Fig. 9.14 in Chapter 9).

In general, regional stations and local networks complement each other in the analysis of smaller sources at local distances. Additionally, source processes and source parameters can be estimated using local station data. For this purpose, first motion polarities (compression c or +, dilatation d or -) for phases Pg, Pn, Sg and amplitude ratios (P/SV) should be measured for fault plane solution and moment tensor inversion (see 3.4 and 3.5). In regions with poor azimuthal and distance coverage by stations, the mean precision of location may be several kilometers and source depths may then only be estimated via depth phase modeling and fitting (Fig. 2.85).

An important aspect to consider in digital recordings and data analysis of local and regional seismograms is the sampling rate. Sampling with more than 80 s.p.s. is generally suitable for near seismic events. With lower sampling rate some of the most essential information about the seismic source process such as the corner frequency of the spectrum and its high-frequency decay, may be lost. Fig. 11.60 gives an example, which shows that only the 80 Hz data stream with a Nyquist frequency of 40 Hz allows the corner frequency near 20 Hz to be determined. In some regions, however, or when studying small local earthquakes, still higher frequencies have to be analyzed. This may require sampling rates between 100 and 250 Hz.

a)

b)

**Fig. 11.60 a):** BB-velocity seismogram from a local earthquake near Bad Ems, Germany (11 Oct. 1998;  $M_l = 3.2$ ) recorded at the GRSN station TNS ( $D = 40$  km). Different sampling rates were used for data acquisition. Traces 1 – 3 were sampled at 20 Hz and traces 4 – 6 at 80 Hz. In the records with the higher sampling rate, the waveforms are much more complex and contain higher frequencies. The high frequency content is suppressed with the lower sampling rate. **b):** Fourier spectrum of traces 1 (sampling rate 20 Hz – pink) and 4 (sampling rate 80 Hz – red). The lower sampling rate cuts off the high-frequency components of the seismic signal. Thus the corner frequency of the signal at about 20 Hz and the high-frequency decay could not be determined from the pink spectrum. The green spectrum represents the seismic noise.

Note that besides the crustal phases so far mentioned a very different type of seismic wave, the so-called T-phase, may appear in records of oceanic earthquakes at near coastal stations. The T-phase forms a rather long envelope-shaped wave train with a faint onset and ending and follows well behind the crustal phase wave train. For records and more explanations about the origin of these phases Chapter 2, section 2.6.5, Figs. 2.71 and 2.72.

In Box 1 a summary is given of essential features that can be observed in records of local and regional seismograms. For more records in this distance range see DS 11.1.

### BOX 1: General rules for local and regional events

- The frequency content of local events ( $D < 2^\circ$ ) is usually high ( $f \approx 0.2 - 100$  Hz). Therefore they are best recorded on SP or SP-filtered BB instruments with sampling rates  $f \geq 80$  Hz. The overall duration of short-period local and regional ( $D < 20^\circ$ ) seismograms ranges between a few seconds and several minutes.
- Stronger local/regional sources radiate long-period energy too and are well recorded by BB and LP seismographs. In the far regional range the record duration may exceed half an hour (Chapter 1, Fig. 1.2).

- Important seismic phases in seismograms of local sources are Pg, Sg, Lg and Rg and in seismograms of regional sources additionally Pn and Sn, which arrive beyond  $1.3^{\circ}$ - $2^{\circ}$  as the first P- and S-wave onsets. The P waves are usually best recorded on vertical and the S waves on horizontal components.
- Note that Pg is not generally seen in records from sources in the oceanic crust. Also, deep (sub-crustal) earthquakes lack local and regional crustal phases.
- For rough estimates of the epicentral distance D [km] of local sources, multiply the time difference Sg-Pg [s] by 8, and in the case of regional sources the time difference Sn-Pn [s] by 10. For more accurate estimates of D use local and regional travel-time curves or tables or calculations based on more appropriate local/regional crustal models.
- The largest amplitudes in records of local and regional events are usually the crustal channel waves Lg (sometimes even beyond  $15^{\circ}$  in continental platform areas), and for near-surface sources the short-period fundamental Rayleigh mode Rg. For near-surface explosions or mining-induced earthquakes, Rg, with longer periods than Sg, may dominate the record, however usually not beyond  $4^{\circ}$ .
- In records of oceanic earthquakes at near coastal stations occasionally T phases may be observed.
- For routine analysis the following station/network readings should be made: (1) the onset time and polarity of observed first motion phases; (2) onset times of secondary local and regional phases; (3) local magnitude based either on maximum amplitude or duration. If local/regional calibration functions, properly scaled to the original magnitude definition by Richter (1935) or the IASPEI standard formula, are not available it is recommended to use the original Richter equation and calibration function, together with local station corrections.

### 11.5.3 Teleseismic earthquakes ( $20^{\circ} < D < 180^{\circ}$ )

#### 11.5.3.1 Distance range $20^{\circ} < D \leq 100^{\circ}$

The main arrivals at this distance range up to about  $80^{\circ}$  have traveled through the lower mantle and may include reflections from the core-mantle boundary (CMB) (Figs 11.61, 11.62 and 11.64). The lower mantle is more homogeneous than the upper mantle (Fig. 2.79). Accordingly, P and S waves and their multiples form rather simple long-period seismograms (Figs. 11.12 and 11.63; see also files 5 and 6 in IS 11.3). Between  $30^{\circ}$  and  $55^{\circ}$ , the waves reflected from the core (e.g., PcP, ScP etc.) are also often recorded as sharp pulses on short-period records, particularly on records of deep earthquakes where depth phases appear well after the core reflections (Fig. 11.21). At around  $40^{\circ}$ , the travel-time curve of PcP intersects those of PP and PPP (Figs. 11.8 and 11.64) and in horizontal components PcS intersects S, and ScS intersects SS and SSS (Fig. 11.8). This complicates proper phase separation, at least for the later phases on long-period records, where SS and SSS may be strong. ScP, however, may also be rather strong on short-period vertical components (Fig. 11.64). The amplitudes of the core reflections decrease for larger distances but they may be observed up to epicentral distance of about  $80^{\circ}$  (ScP and ScS) or  $90^{\circ}$  (PcP), respectively, beyond which ScS merges with the travel-time curves of SKS and S and PcP with that of P (see Figs. 11.8, 11.20, 11.21 and 11.66). Note that PP, PS, SP and SS are Hilbert-transformed (see 2.5.4.3). Their onset and amplitude picks can be improved by inverse Hilbert transformation, which is part of modern analysis software such as Seismic Handler (SH and SHM).

**Fig. 11.61** Seismic ray paths through the mantle and core of the Earth with the respective phase names according to the international nomenclature (Chapter 2, Figs. 2.58 and 2.60, and IS 2.1 for phase names and their definition). The red rays relate to body wave onsets in the 3-component analog Kirnos SKD BB-displacement record below from an earthquake at  $D = 112.5^\circ$  at station MOX, Germany.

**Fig. 11.62 Left:** Array and single station observations of PcP for an  $m_b = 5.3$  and  $h = 29.7$  km deep Cyprus earthquake on 1993 March 22. The beam traces of the arrays are named by their reference stations GEC2 (GERES), GRA1, GRB1, GRC1 (Gräfenberg), FIA1 (FINES), and NRA0 (NORES), respectively. All data are bandpass filtered between 0.8 and 3 Hz. The un-restituted, velocity proportional traces are scaled to their maximum amplitude, which is given in digital counts. **Right:** The same for ScP observations of an  $m_b = 5.0$  and  $h = 106.6$  km deep earthquake in Turkey on 1991 December 5. The beam traces of the arrays are named by their reference stations GEC2 (GERES), GRA1, GRB1, and GRC1 (Gräfenberg), respectively. Color versions of Figures 2 and 3 of Schweitzer (2002); © Geophys. J. Int.

**Fig. 11.63** Long-period Z- (top record section) and T-component seismograms (middle record section) of a shallow earthquake in western India recorded in the distance range 51° to 56° at stations of the GRSN. The two cut-out vertical component short-period record sections at the bottom left and middle show the in the later part of the surface waves arriving multiple core phases PKPPKpdf (= P'P') and P4KP. For all phases identified in these records the related ray paths are depicted on the right side diagram (for animation see file 5 in IS 11.3).

**Fig. 11.64** Vertical-component Kirnos SKD BB-displacement (top record section) and WWSSN-SP seismograms (lower left two record sections) from an intermediate depth ( $h = 227$  km) earthquake in the Afghanistan-Tajikistan border region recorded at stations of the GRSN. Besides P the depth phases pP, sP, pPP, sPP and pPPP the core reflections PcP and ScP are clearly visible, particularly on the short-period records. The ray traces of these phases are shown in the lower right diagram (see also file 4 in IS 11.3 and related animation).

**Remark:** For many of the above and following record sections with accompanying ray diagrams one finds in DS 11.2 and 11.3 more clear records with better time resolution.

Fig. 11.65 shows the ray paths for S, ScS and SKS and their related travel-time curves according to the IASP91 model for the distance range from 60° to 180° and Fig. 11.66 both short- and long-period records of these waves between 50° and 80°.

**Fig. 11.65** Ray paths for S, ScS and SKS and their related travel-time curves according to the IASP91 model for the distance range from 60° to 180°.

Arrays and network records, which also allow f-k and vespagram analysis, are very useful for identifying the core reflections PcP, ScP and ScS because their slownesses differ significantly from those of P, S and their multiple reflections (Fig. 11.62 and Figures 6a and b and 7b in DS 11.2). Surface reflections PP, PPP, SS and SSS are well developed in this distance range in long-period filtered records and converted waves PS/SP at distances above 40°. Sometimes the surface reflections are the strongest body-wave onsets at large distances (Figures 10c and 11b in DS 11.2). Their identification can be made easier when network records are available so vespagram analysis can be used (e.g., Figure 11c in DS 11.2). In short-period filtered network records it is sometimes possible to correlate in this distance range multiple reflected core phases such as PKPPKP (or P'P'), SKPPKP and SKPPKPPKP (Chapter 1, Fig. 1.10)

**Fig. 11.66** SP (left) and LP (right) horizontal-component seismograms from a deep-focus earthquake in the Sea of Okhotsk (20 April 1984,  $m_b = 5.9$ ,  $h = 588$  km) recorded at stations in the distance range  $50.1^\circ$  to  $82.2^\circ$ . Note the different amplitude scaling. Accordingly, the amplitudes of various transverse phases are 2 to 10 times larger in long-period records when compared with short-period records. Four distinct phases are identified: S, ScS, sS and SS. SKS, however, which emerges at distances larger than  $60^\circ$ , overlaps with ScS between about  $65^\circ$  and  $75^\circ$ . S, ScS and SKS start to coalesce as distance increases toward  $82^\circ$ . Beyond this distance SKS arrives before S, SKKS and ScS (reprinted from *Anatomy of Seismograms*, Kulhánek, Plate 40, p.137-138; © 1990; with permission from Elsevier Science).

Beyond  $83^\circ$  SKS arrives for near surface sources - but earlier already for deeper earthquakes - ahead of S and its amplitude relative to S increases with distance. Network and array analysis yields different slowness values for S and SKS because of their diverging travel-time curves (Fig. 11.65). This helps to identify these phases correctly. Note that the differential travel time SKS-P increases only slowly with distance (Fig. 11.8). Misinterpretation of SKS as S may therefore result in an underestimation of D by up to  $20^\circ$ ! Since SKS is polarized in the vertical plane it can be observed and separated well from S in radial and vertical components of rotated seismograms (Fig. 11.67 and Figures 10c, 13e, 14e, and 15b in DS 11.2). This also applies to PcS and ScP that are polarized in the vertical propagation plane as well (Fig. 11.64).

In the distance range between about  $30^\circ$  and  $105^\circ$  multiple reflected core phases P'N or between about  $10^\circ < D^\circ < 130^\circ$  the phases PNKP, with N-1 reflections either at the free surface (P'N) or from the inner side of the core-mantle boundary (PNKP), respectively, may appear in short-period records some 13 min to 80 min after P. An example for PKPPKP (P'P') and PKKKKP (P4KP) is given in Fig. 11.63. These phases are particularly strong near caustics, e.g., P'P' (Fig. 11.77) and P'P'P' (P'3) near  $70^\circ$  and PKKP near  $100^\circ$  (Fig. 11.78) but they are not necessarily observable at all theoretically allowed distances. Figures 9 and 10 in EX 11.3, however, document the rather wide distance range of real observations of these

phases at station CLL (for P'P' between 40° and 105° and for PKKP between 80° and 126°). Note the different, sometimes negative slowness of these phases. More record examples, together with the ray paths of these waves, are presented in a special section on late core phases (11.5.4). For differential travel-time curves of PKKP-P and PKPPKP-P Figures 9 and 10 in EX 11.3. Also PKiKP, a weak core phase reflected from the surface of the inner core (ICB), may be found in short-period array recordings throughout the whole distance range, about 4.5 to 12 min after P. Its slowness is less than 2s/°. Beyond 95°, P waves show regionally variable, fluctuating amplitudes. Their short-period amplitudes decay rapidly (Fig. 11.10) because of the influence of the core (core-shadow) while long-period P waves may be diffracted around the curved core-mantle boundary (Pdif, Figs. 11.70 and 11.74 as well as Figures 1, 2, 4b and 6c and b in DS 11.3).

In any case, comprehensive seismogram analysis should be carried out for strong earthquakes which produce many secondary phases. Unknown phase arrivals should also be reported for further investigations into the structure of the Earth. When reporting both identified and unknown phases to international data centers the IASPEI-proposed international nomenclature should strictly be observed (see IS 2.1).

### 11.5.3.2 Distance range $100^\circ < D \leq 144^\circ$

Within this distance range, the ray paths of the P waves pass through the core of the Earth. Due to the large reduction of the P-wave velocity at the core-mantle boundary (CMB) from about 13.7 km/s to 8.0 km/s (Fig. 2.79 in Chapter 2) seismic rays are strongly refracted into the core (i.e., towards the normal at this discontinuity). This causes the formation of a "core shadow". This "shadow zone" commences at an epicentral distance around 100°. The shadow edge is sharper for short-period P and S waves than for long-period P and S waves that are diffracted much further around the curved CMB (compare Figures 6b and c as well as 7a and b in DS 11.3). For strong earthquakes Pdif and Sdif may be observed out to distances of more than 150° (Figs. 11.67, 11.68, 11.70 and 11.74).

**Fig. 11.67** SRO-LP filtered 3-component seismograms at station GRA1, Germany, in  $D = 117.5^\circ$  from an earthquake in Papua New Guinea (17 July 1998,  $M_s = 7.0$ ). The N and E components have been rotated into the R and T directions. Phases Pdif, PP, PPP and a strong PS and SP are visible on the vertical component, whereas the phases SKS, SKKS and PS, which are polarized in the vertical propagation plane, are strong on the radial (R) component (as are PP and PPP). In contrast, Sdif, SS and SSS are strong on the transverse (T) component.

Fig. 11.68 shows rotated (R-T) horizontal component SRO-LP recordings at GRSN stations from two intermediate deep events in the Chile-Bolivia border region and in the Mariana Islands, respectively. The related ray paths are depicted in the upper part. The records cover the transition from the P-wave range into the P-wave core shadow. Magnified cut-outs, also of the related Z-component records, are presented for both earthquakes in Figures 1 and 2 of DS 11.3. They show more clearly the first arriving longitudinal waves and their depth phases. The following conclusions can be drawn from a comparison of these figures:

- Pdif arrives about 4 minutes (at larger distance up to 6 min; Fig. 11.74) earlier than the stronger PP;
- The largest phases (Figs 11.68 and . 11.71) are usually PP, PPP, PS, SP, Sdif, SKS, SKKS, SS and SSS;
- SKS is the first arriving shear wave, followed by SKKS, SP or PS (and the related depth phases), all on the R component;
- S/Sdiff and SS may be strong(est) in T or R, or even in both components, depending on the SV/SH ratio of shear-wave energy radiated by the source.

**Fig. 11.68** SRO-LP filtered records of GRSN stations on R and T components in the distance range between  $96^\circ$  and  $109^\circ$  from two earthquakes on opposite backazimuth (Chile-Bolivia Border region and Mariana Islands, respectively; source data according to the NEIC).

If no Pdif is observed, PKiKP is the first arrival in short-period records up to  $113^\circ$  (Figure 3b in DS 11.3). For distances beyond  $114^\circ$  PKiKP follows closely after PKPdf (alternatively termed PKIKP). The latter has traveled through the outer and inner core and arrives as first onset for  $D \geq 113^\circ$ . PKPdf is well recorded in short-period seismograms but usually with emergent onsets and, up to about  $135^\circ$  distance, still with weaker amplitudes than PKiKP. Fig. 11.69 shows theoretical amplitude-distance relationship between PKiKP, PKPdf and the other

direct core phases PKPab and PKPbc, which appear with largest amplitudes beyond  $143^\circ$ . Fig. 11.70 depicts the ray paths and travel-time curves of Pdif, PKiKP, PKPdf, PKPab and PKPbc (for more complete ray paths see IS 2.1). Also PKKP (with its branches ab and bc) is often clearly recorded between  $110^\circ$  and  $125^\circ$  (Figures 3c and d in DS11.3).

Fig. 11.71 presents records of GRSN stations in the distance range  $121^\circ$  to  $127^\circ$  from an earthquake at intermediate depth ( $h = 138$  km) in the region of New Britain (see file 8 in IS 11.3 and animation CD). They show the PKPdf arrivals about 3.5 min after Pdif together with the dominant phases in this range, namely PP, PPP, PS, PPS and the Rayleigh-wave arrival LR in the Z component and the SS, SSS and the Love-wave arrival LQ in the T component. Also shown, together with the ray paths, is the core phase P4KPbc, which has been reflected 3 times at the surface of the Earth, and which is recognizable only on the short-period filtered vertical component. Between about  $128^\circ$  and  $144^\circ$  some incoherent waves, probably scattered energy from “bumps” or heterogeneities at the CMB or in the D” layer above it (Chapter 2, Fig. 2.79), may arrive as weak forerunners up to a few seconds before PKPdf. They are termed PKPpre (old PKhKP). PKPdf is followed by clear PP, after about 2 to 3 minutes, with SKP or PKS arriving about another minute later (Fig. 11.72).

**Fig. 11.69** Theoretical smoothed amplitude-distance relationships for the core phases PKiKP, PKPdf, PKPab and PKPbc as calculated for the model 1066B in the distance range  $130^\circ$  to  $160^\circ$  (modified from Houard et al., 1993, *Bull. Seism. Soc. Am.*, Vol. 83, No. 6, Fig. 4, p. 1840, © with permission Seism. Soc. Am.).

SKP/PKS have their caustics at about  $132^\circ$  and thus, near that distance, usually have rather large amplitudes in the early part of short-period seismograms (Fig. 11.72). For medium-sized earthquakes these phases may even be the first ones to be recognized in the record and be mistaken for PKP. Note that for near-surface events SKP and PKS have the same travel time, but with the former having relatively larger amplitudes in the Z component whereas PKS is larger in the R component. For earthquakes at depth, PKS and SKP separate, with the latter arriving the earlier the deeper the source (Fig. 11.72). Beyond  $135^\circ$  there are usually no clear phases between SKP and SS. Misinterpretation (when Pdif is weak or missing) of PP and SKS or PS waves as P and S may in this distance range result in strong underestimation of D (up to  $70^\circ$ ). This can be avoided by looking for multiple S arrivals (SS, SSS) and for surface waves which follow more than 40 min later (Table 5 in DS 3.1). For more records see DS 11.3, examples 1 to 7.

Figure 1 displays seismic tomography results for the New Britain region. The figure includes four panels of seismic waveforms (BFO, FUR, GRFO, MOX, CLL) and a map of the region.

The top-left panel shows Z-component filtered SRO\_LP waveforms with phases PdF, PKPcF, JP, PFP, PS, PPS, and LR marked. The top-right panel shows T-component filtered SRO\_LP waveforms with phases SS and SSS marked. The bottom-left panel shows Z-component filtered SRO\_LP waveforms with phases PdF, PKPcF, and 4(PKPbc) marked. The bottom-right panel shows Z-component filtered WWSBL\_LP waveforms with phases PdF, PKPcF, JP, PFP, PS, PPS, SS, SSS, LQ, and LR marked.

The map on the right shows the New Britain region with various seismic phases and their travel times. The map includes labels for Central Russia, Mongolia, E China Sea, Philippine Sea, W of Isonaka Is., New Britain, Southern Pacific Ocean, and Brazil.

### 11.5.3.3 Core distance range beyond 144°

Between 130° and 143° the first onsets of longitudinal core phases are relatively weak and complex in short-period records, but their amplitudes increase strongly towards the caustic around 144°. At this epicentral distance three PKP waves, which have traveled along different ray paths through the outer and inner core, namely PKPpdf, PKPbc (old PKP1) and PKPab (old PKP2) arrive approximately at the same time (Fig. 11.70 above) so their energies superimpose to give a strong arrival with amplitudes comparable to those of direct P waves at epicentral distances around 40° (compare with Fig. 11.10). Beyond the caustic the travel-time curves of these three PKP waves split into the branches AB (or ab), BC (or bc) and DF (or df) (Fig. 11.70). Accordingly, the various arrivals can be identified uniquely by attaching to the PKP symbol for a direct longitudinal core phase the respective branch symbol (IS 2.1 and Figs. 11.70 and 11.73). Note that the PKPbc branch shown in Figs. 11.70 between the point B and C is ray-theoretically not defined beyond 155°. However, in real seismograms one often observes weak onsets between PKPpdf and PKPab up to about 160° or even slightly beyond in the continuation of the PKPbc travel-time curve. This phase is a PKP wave diffracted around the inner core boundary (ICB) and named PKPdif (IS 2.1 and Fig. 11.76 and 11.77).

**Fig. 11.73 Left:** Records of the direct core phases PKPdf, PKPbc and PKPab as well as of the diffracted phase PKPdif from a Kermadec Island earthquake at stations of the GRSN in the distance range between 153° and 159°; **right:** PKP ray paths through the Earth.

The relative amplitudes between the three direct longitudinal core phases change with distance. In SP records these three phases are well separated beyond 146°, and PKPbc is the dominant one up to about 153° though the separation between these three phases is not clear within this range in LP records (Fig. 11.74 right and Figures 9a-c in DS 11.3).

On short-period records the phases PKPdf, PKPbc and PKPab are easy to identify on the basis of their typical amplitude and travel-time pattern. D can be determined with a precision better than 1.5° by using differential travel-time curves for the different PKP branches (see EX 11.3). On records of weaker sources, PKPbc is often the first visible onset because the PKPdf, which precedes the PKPbc, is then too weak to be observed above noise. On long-period records the different superimposed onsets may be recognizable only at distances larger than 153°. Then PKPab begins to dominate the PKP-wave group on short-period records (compare Figs. 11.74). Towards the antipode, however, PKPdf (PKIKP) becomes dominating again whereas PKPab disappears beyond 176°.

**Fig. 11.74** Short-period (left side) and long-period (SRO-LP; right side) filtered broadband records of PKP phases at GRSN stations in the distance range  $116^{\circ}$  to  $163^{\circ}$ . In the LP records additionally the onsets of Pdif and PP have been correlated with their travel-time curves.

On LP and BB records the dominant phases on vertical and radial components are PKP, PP, PPP and PPS while on the transverse component SS and SSS are dominant. For deep sources, their depth phases sSS and sSSS may be strongest (Fig. 11.75). Besides PP, which has traveled along the minor arc (epicentral distance  $D$ ) the phase PP2, which has taken the longer arc to the station ( $360^{\circ} - D$ ), may be observable, as well as phases such as PcPPKP and others (Fig. 11.76 as well as the animation file 10 in IS 11.3). SKKS, SKKKS, SKSP etc. may still be well developed on radial component records (Chapter 2, Figs. 2.60 and 2.61). The whole length of BB or LP seismograms in this distance range between the first onsets and the surface wave maximum is more than an hour (Tab. 5 in DS 3.1).

### 11.5.4 Late and very late core phases

For large magnitude sources, core phases reflected at the Earth's surface or at the core-mantle-boundary (CMB) may be observed in addition to the direct ones, sometimes with up to 4 (or even more) repeated reflections. These phases may be observed at practically all teleseismic distances with delays behind the first arriving P or PKP onsets ranging from about 10 minutes up to about 80 minutes, depending on the number of multiple reflections (for travel-time curves Chapter 2, Fig. 2.59). These phases are clearly discernible only in high-magnifying SP (or appropriately filtered BB) records (Fig. 2.57). Most frequently observable are the single surface

reflection P'P' (also termed PKPPKP), and the single reflection from the inner side of the core-mantle boundary, PKKP. As for the direct core phases, these multiple reflections develop different travel-time branches according to their different penetration depth into the outer core (see also ray tracing figures in IS 2.1). Figs. 11.77 and 11.78 show the ray paths for P'P' and PKKP waves, respectively, together with their related IASP91 travel-time curves (Kennett and Engdahl, 1991) for sources at depth  $h = 0$  km and  $h = 600$  km. Where there is more than one reflection the respective phases are often written P'N or PNKP, respectively, with the number of reflections being  $N-1$ . Ray paths and short-period record examples for P'N with  $N = 2$  to 4 are shown in Figs. 11.79 to 11.81 and for PNKP with  $N = 2$  to 5 in Figs. 11.81 and 82. Fig. 11.75 shows a P5KP (PKKKKKP), which has been four times reflected from the inner side of the CMB. It is observed nearly 37 min after PKP. The phase P7KP has been found in a record at Jamestown, USA, of an underground nuclear explosion on Novaya Zemlya in 1970. Complete ray diagrams of many direct, converted and multiply reflected core phases have been presented in IS 2.1.

Additionally, the figures presented below show that these late arrivals may still have a significant SNR. Since they appear very late and thus isolated in short-period records, station operators may wrongly interpret them as being P or PKP first arrivals from independent events. This may give rise to wrong phase associations and event locations, which, particularly in a region of low seismicity, may give a seriously distorted picture of its seismicity. This was demonstrated by Ambraseys and Adams (1986) for West Africa.

**Fig. 11.75** Records of GRSN stations of a deep earthquake in the Fiji Island region. **Right:** ray paths and source data; **Left:** Records on the Z component (LP top left and SP lower left) and T component (LP middle left) (see also animation file 9 in IS 11.3).

**Fig. 11.76** Records of GRSN stations of a shallow (crustal) earthquake east of the North Island of New Zealand. **Lower right:** ray paths to station MOX in Germany and source data; **Top and middle left:** Records on SRO-LP components Z and T). **Lower left:** The first 14 min of the SRO-LP Z-component P-wave record. For animation see file 10 in IS 11.3).

In Figs. 11.73 to 11.82 the theoretical travel-time curves, respectively arrival times for core phases have been plotted. For consistency, they are based on the travel-time model IASP91 (Kennett and Engdahl, 1991), as in all earlier record sections shown for the teleseismic distance range. An exception is Fig. 11.79, which shows additionally the theoretical travel-time curve for the JB model (Jeffreys and Bullen, 1940) as in the lower middle record segment too for P5KP. One recognizes that the model IASP91 yields onset times for core phases that tend to be up to several seconds earlier than the real onsets in the seismograms (see also Fig. 9b and c in DS 11.3). This applies to both direct and multiple reflected core phases. The agreement between real and theoretical onsets of core phases is better when using the JB model. Also S onsets arrive with respect to the IASP91 model a bit too late. The more recent model AK135 (Kennett et al., 1995) is more appropriate than IASP91. The JB model has regularly been used until recently for the location of teleseismic sources at the international data centers in Boulder (NEIC), Thatcham (ISC) and Moscow whereas the IDC of the CTBTO uses IASP91. AK135 is now the default model used by the ISC and the NEIC.

**Fig. 11.77** Ray paths and travel-time curves for P'P' according to the Earth model IASP91 (Kennett and Engdahl, 1991).

**Fig. 11.78** Ray path and travel-time curves for PKKP according to the Earth model IASP91 for epicentral distances of the source between  $60^\circ$  and  $140^\circ$ .

**Fig. 11.79 Right:** Source data of the Myanmar earthquake and ray paths to station CLZ in Germany. **Left:** Short-period Z-component record segments of GRSN stations with P, P' and P'3 arrivals at  $65^\circ < D < 70^\circ$  together with their theoretically expected arrival times according to the IASP91 and JB tables. Note the much better fit with the JB times.

**Fig. 11.80 Left:** 1 min long SP record segments showing P and PKPdf (outer left) together with P'2, P'3 and P'4 (middle left) at GRSN stations. **Right:** Related ray paths and source data. Note the negative slowness for P'2 and P'4. The travel-time curves relate to IASP91.

### Late and very late core phases

**Fig. 11.81** Late and very late multiple core phases PKKP, P'2 and P'3, respectively, together with their depth phases in short-period filtered record segments of GRSN stations from an earthquake in Northern Peru at epicentral distances around 92°. For an animation of ray propagation and seismogram formation from this source see file 6 in IS 11.3.

### PKKP, P3KP, and P5KP

**Fig. 11.82 Left:** Short-period 1 min record segments of P and PKP (outer left) together with those of PKKP, P3KP and P5KP (middle left) at GRSN stations. Note in the upper middle segment the excellent fit of the second onset with the extrapolation of the IASP91 PKKPbc branch and the much better fit of the P5KP onset in the lower middle segment with the JB-times **Right:** Related source data and ray paths. Note the negative slowness for PKKP and P3KP. The other theoretical travel-time curves relate to IASP91.

Note that the difference between the azimuth of the P wave and that of P'P' and PKKP, respectively, is  $180^\circ$  (Figs. 11.77 and 11.78). The related angular difference of the surface projections of their ray paths is  $360^\circ - D$  where  $D$  is the epicentral distance. Accordingly, the slowness of P'P' as well as of any even number P'N is negative, i.e. their travel time decreases with  $D$ . This also applies to PKKP and P3KP, as can be seen from Fig. 11.82. The surface projection of the travel paths of P'3 is  $360^\circ + D$  and that of P'4 is  $2 \times 360^\circ - D$ . PKPPKP (= P'P') is well observed between about  $40^\circ < D \leq 105^\circ$ . In this range the phase follows the onset of P by 33 to 24 min (Figure 10 in EX 11.3 with observed data). The existence of P'N is not limited to PKPbc. Fig. 11.79 shows an example of P'3df, recorded at a distance of about  $67^\circ$ . P'4 is sometimes observed in the distance range  $112^\circ$  to  $136^\circ$ . An example is given in Fig. 11.80.

Similar ray paths can be constructed for PNKP, the phase with  $(N-1)$  reflections from the inner side of the core-mantle boundary (Fig. 11.82). Figure 9 in EX 11.3 gives the differential travel-time curves for PKKP to the first arrivals P or PKP, respectively, in the distance range between  $80^\circ$  and  $130^\circ$  together with the observed data. In this range PKKP arrives 13 to 19 min behind P or 9.5 to 12 min behind PKP<sub>df</sub>. Higher multiple reflections from the inner side of the CMB such as P3KP, P4KP and P5KP are observed, if at all, at  $37 \pm 1$  min after the first arriving wave. The latter is true for P3KP following P at around  $10^\circ$ , for P4KP following P between  $45^\circ < D < 75^\circ$  and for P5KP following the onset of PKP<sub>df</sub> between about  $130^\circ < D < 150^\circ$  (called “37- min” rule- of- thumb).

The travel-time difference of multiple reflected core phases to the first arriving P and PKP does not change much with source depth. Therefore, you may try it just for fun although there is no more *need* for it in the present time world of near real-time global network locations and data dissemination, but the identification of these phases and knowing their travel-time curves, allows rather good distance estimates to be made even from single station records, irrespective of whether you know the source depth or not. Because of the inverse differential travel-time curves of PKPPKP and PKKP with respect to P and PKP their identification can be facilitated by comparing the onset times at neighboring stations (e.g., upper left two panels in Fig. 11.81).

The polarization of both the first arrival and the possible PKKP or PKPPKP onset, determined from 3-component records, can also aid identification because their azimuths should be opposite to that of P or PKIPK, respectively. Sometimes, also converted core reflections such as SKPPKP or SKKP can be observed in short-period recordings. However, direct or reflected core phases, which have traveled along the two ray segments through the mantle as S waves (such as SKS, SKKS, etc.) are mostly observed in broadband or long-period records.

### 11.5.5 Final remarks on the recording and analysis of teleseismic events

Box 2 summarizes the key criteria that should be taken into account when recording and analyzing seismograms from sources at teleseismic distances (see also 11.2.6.1).

## Box 2: General rules for recording and analyzing teleseismic events

- The overall duration of teleseismic records at epicentral distances larger than  $15^\circ$  (or  $20^\circ$ ) ranges from tens of minutes to several hours. It increases both with epicentral distance and the magnitude of the source.
- High frequencies, of S waves in particular, are more strongly attenuated with distance. Therefore recordings at teleseismic distances are usually of lower ( $f \approx 0.01 - 1$  Hz) frequency than local or regional recordings although for some events frequencies up to about 10 Hz have also been observed in P and PKP waveforms.
- Usually only longitudinal waves, both direct or multiple reflected P and PKP phases, which are much less attenuated than S waves, are well recorded by short-period, narrow-band seismographs (or their simulated equivalents) with high magnification of frequencies around 1 Hz. However, S waves from deep earthquakes may sometimes be found also in SP teleseismic records.
- Because of the specific polarization properties of teleseismic body and surface waves, polarization analysis is an important tool for identifying the different types of wave arrivals.
- According to the above, teleseismic events are best recorded by high-resolution 3-component broadband seismographs with large dynamic range and with sampling rates  $f = 20\text{-}40$  Hz.
- The main types of seismic phases from teleseismic sources are (depending on distance range) the longitudinal waves P, Pdif, PKP, PcP, ScP, PP, and PPP and the shear waves S, Sdif, SKS, ScS, PS, SS, and SSS. The longitudinal waves are best recorded on vertical and radial components whereas the shear waves appear best on transverse and/or radial components.
- Multiple reflected core phases such as P'N and PNKP, which appear on SP records as isolated wavelets, well separated from P or PKP, may easily be misinterpreted as P or PKP arrivals from independent seismic sources if no slowness data from arrays or networks are available. Their proper identification and careful analysis helps to avoid wrong source association, improves epicenter location and provides useful data for the investigation of the physical properties of the deeper interior of the Earth.
- Several body wave phases such as PP, PS, SP, SS, PKPab, SKKSac, SKKSdf, PKPPKpab, SKSSKSab and their depth phases undergo phase shifts and wavelet distortions at internal caustics (see 2.5.4.3). This reduces the accuracy of their time and amplitude picks and their suitability for improving source location by waveform matching with undistorted phases. Therefore it is recommended that seismological observatories correct these phase shifts prior to parameter readings by applying the inverse Hilbert-transformation, which is available in modern software for seismogram analysis.
- Surface waves of shallow events have by far the largest amplitudes but surface wave amplitudes from deep earthquakes and large (nuclear) explosions are small at teleseismic distances.
- At seismic stations or network centers the following parameter readings should be obligatory during routine analysis: onset time, SNR, and, if possible, polarity of the first arriving phase; maximum P amplitude A [nm],

period  $T$  [s] and/or ground velocity  $V$  [nm/s]; onset time of secondary phases; and, if existing, additionally also for surface waves the maximum amplitude  $A$  [nm], period  $T$  [s] and/or  $V$  [nm/s], irrespective of source depth.

- P-wave amplitudes  $A_{\max}$  for the determination of the short-period body-wave magnitude  $m_b$  have to be measured on standard short-period (WWSSN-SP simulated) records at periods  $0.2 \text{ s} < T < 3 \text{ s}$  and for broadband  $mB\_BB$   $V_{\max}$  in the period range between 0.2 s and 30 s, whereas the surface-wave amplitudes  $A_{\max}$  for the determination of the surface-wave magnitude  $M_s_{20}$  have to be measured on standard long-period filtered (WWSSN-LP or SRO-LP simulated) records, typically in the period range between 18 and 22 s, whereas  $V_{\max}$  for broadband  $M_s\_BB$  has should be measured between 3 s and 60 s period.
- For more guidance on magnitude determination, using also other phases and records/filters, consult Chapter 3 and IS 3.3 in particular.
- Networks and arrays should additionally measure and report slownesses and azimuths for analysed onsets.
- For improved determination of epicentre distance and source depth the measurement and reporting of onset time readings for secondary onsets such as S, depth phases (pP, sP, sS, etc.) and of core reflections (PcP, ScP, etc.) in particular, are very important.
- Picking and reporting of onset-times, amplitudes and periods of other significant phases, including those not identified, are encouraged by IASPEI within the technical and personnel facilities available at observatories and analysis centers as being a useful contribution to global research. These extended possibilities for parameter reporting are now well supported by the recently adopted IASPEI Seismic Format (ISF), which is much more flexible and comprehensive than the traditional Telegraphic Format (see 10.2 as well as IS 10.1 and 10.2), or by QuakeML (see IS 3.2, section 2).
- For reporting of seismic phases (including onsets not identified) one should exclusively use the new IASPEI phase names. For the definition of seismic phases and their ray paths see IS 2.1. Amplitude data should be reported according to the agreed IASPEI nomenclature for standard magnitudes (IS 3.3) and also other non-standard amplitude measurements (see IS 2.1).

## 11.6 Is fully automatic seismogram analysis, event location and classification already possible and feasible?

### 11.6.1 Introduction

Despite the potential benefits which digital data and interactive analysis software nowadays offer it is a matter of fact that digital records are increasingly less frequently read manually in a comprehensive way by seismologically trained experienced people. As outlined in Chapter 1, one main reason for this development is the tremendous increase in the number of high-gain seismic stations and networks deployed now all over the world for a steadily growing number of tasks which nowadays go even far beyond classical earthquake monitoring. They include volcano- seismology (Chapter 13 and Hammer et al., 2012); monitoring of induced seismicity (e.g., McGarr et al., 2002; Beyreuther et al., 2012) related to industrial activities such as the exploitation of geothermal, gas and oil reservoirs, mining activities (e.g., Kwiitek

et al., 2010), waste water disposal, impoundment and level-changes of huge water reservoirs (e.g., Gupta and Rastogi, 1976), or mass movements in mountain areas (e.g., Hammer et al., 2013). Accordingly, the amount of data to be analyzed has grown in recent decades by several orders of magnitude as compared to the times of classical analog earthquake seismology. Another reason is the increasing unwillingness of decision makers and funding institutions to pay fair salaries for a much larger number of well-educated people required to do all these jobs. Pressing demands for reducing labor cost both in the public sector and in industry and the often non-realistic belief that in the computer age automated procedures could do the job already not only faster but even better than well trained and experienced human beings are dominating nowadays.

The latter is surely not yet true. Nevertheless, we are now in a rapidly advancing process of increasingly better modeling of human intelligence, pattern recognition, and knowledge-based decision making. Machine-learning methods for the automatic classification and analysis of seismic waveforms gain momentum (e.g., Riggelsen and Ohrnheimer, 2012). Automatic algorithms, advanced or not yet advanced, have the advantage of being objective. Their results are fully reproducible, but not the analysis results of a group of human analysts (see IS 11.5). This even makes it difficult to correctly assess, in a unique manner, the performance of automatic algorithms as compared to human seismic data analysis. An example for such a comparison see is section 3.2.3.2 in Chapter 3. Moreover, both the acceptable ratio between missed events and false alarms on the one hand and between the timeliness and required accuracy/completeness of the data and derived information on the other hand are task-dependent. This also applies to the proper balance to be found between automatic and human analysis of seismological data.

Of greatest importance is in this context the fact of rapid population growth and urbanization since the mid 20<sup>th</sup> century, combined with a dramatic increase of the vulnerability and related human and material losses due to earthquakes and volcanic eruptions. This necessitates the development of earthquake, tsunami and volcanic eruption early warning systems (EEWS; TEWS; VEEWS) for enabling fastest possible appropriate automatic or human controlled response aimed at mitigating the disastrous consequences of such events. Highest priority has the timeliness of sufficiently accurate information for triggering and guiding response actions. This can only be realized with fully or highly automated systems of seismological data analysis and is clearly different from the need for most complete and precise/accurate information required for related future basic research.

Early efforts of automatic seismological detection and classification techniques were based on attributes of specific seismic phases. However, when monitoring volcano-induced seismicity, due to the rather different source processes and complex propagation conditions of the mostly high-frequency waves in a highly heterogeneous medium, a clear identification of individual seismic phases may not be possible. Therefore methods that make use of the whole seismogram are required for event type classification. The majority of algorithms applied to event-based data sets have been based so far on artificial neural networks (ANN). These algorithms, however, are “black boxes”, as are support vector machines that focus on the output only and do not allow any insight into the physical processes which control the relationship between input and output parameters. Alternative approaches will be sketched below. Good summaries with many references one finds, e.g., in Hammer et al. (2012).

A state-of-the-art overview of concepts, theory and approaches to automated seismic event and phase identification gives Chapter 16. Already operational or still experimental tsunami

or earthquake early warning systems such as the Pacific Tsunami Warning System (PTWC; <http://ptwc.weather.gov/>), GITEWS (<http://www.gitews.org/index.php?id=6>), and similar ones in Alaska, Japan, Mexico, Taiwan, Turkey and elsewhere (see Gasperini et al., 2007; Allen et al., 2009; Fleming et al., 2009) are examples of how far developments have already gone this way. In the following we add a few more case studies published in recent years that illustrate the different approaches chosen and the progress made in the automation of seismogram analysis and the classification of seismic events.

### 11.6.2 Amplitude/energy event triggers, phase identification and event location

Allen (1978, 1982) has been the first to propose an automatic P-wave picker for earthquake recognition and timing from short-period narrow-band single trace seismic records. The trigger is based on the long-term/short-term average amplitude, respectively energy ratio STA/LTA (Fig. 11.86; for details Chapter 16 and IS 8.1). It is still the most common and widely applied event trigger algorithm which has to be tuned to the specific signal and noise conditions.

Still most common is the application of the STA/LTA trigger in seismic network recordings. A seismic event is then declared if at least 4 stations have coincident observations in time of trace amplitudes above the set detection threshold that are consistent with seismic wave propagation models. Then, assuming that all these signal detections above noise relate to the first P-wave onset, they can be associated with each other to calculate the 4 unknowns of the hypocenter coordinates and origin time. Various such automatic association programs have been developed, e.g., by Engdahl and Gunst (1966), Slunga (1980), and a knowledge-based system by Bache et al. (1993) to produce automatically teleseismic event bulletins. However, as emphasized by Tong and Kennett (1996), most association programs use only P and S (including also Pn, Pg, Sn, Sg and Lg) as identifying phases. Other frequently observed phases such as PcP, ScS, PKP, PKiPK, PP, PS, SS, SKS, SKP, depth phases and multiple core phases (Fig. 11.16 and Figs. 2.57-2.61 in Chapter 2) are usually not taken into account. Withers et al. (1998a) compared selected trigger algorithms for onset time picking both in the time and frequency domain and also for particle motion and adaptive processing while Withers et al. (1998b) described an automated local and regional seismic event detection and location system using waveform correlation. All of these algorithms require a multi-station network, as do small aperture seismic arrays used for event detection and location of regional events (Chapter 9).

If, however, the number of available stations is small and/or the SNR at many sites is low then signals may be missed on the single station level and as a consequence probably a significant number of weak events will not appear in the automatic draft event bulletins. But then there will also be no visual inspection of records concerned and those weak events remain undetected. On the other hand, when lowering the detection threshold too much then noise fluctuations may cause a great number of spurious detections, *false alarms*, not related to true seismic events or even being wrongly associated to *fake events*, which all have to be reviewed in the interactive visual control step, thus increasing again the analyst workload.

An alternative approach for event detection and location is to rely not only on the automatically picked single component first onset time readings, i.e., just measuring one

parameter at many stations. Rather one should improve also the accuracy and completeness of waveform attributes measured at 3-component broadband records of single stations for many seismic phases,. Such differences may relate to polarization, amplitude ratios, frequency differences and others. Such comprehensive automatic real-time single-station record analysis may yield rather good starting locations for a subsequent iterative location refinement. This particularly holds for short-period seismic arrays because of the inferior distance control of P-wave slowness data as compared to distance estimates based on differential travel times between P and later phases with rather different slowness. But it will also apply when network data are available only from stations with rather bad azimuthal and distance coverage. The latter is often the case for near coastal events because of lacking or insufficient stations in the ocean environment or for seismic events in areas with no co-operation and data exchange between neighboring countries at all. Because of the globally rapidly growing number of stations with free data excess and exchange via Internet this will, however, in future increasingly less be the case. On the other hand, there exist but no near real-time data exchange with others, such as. In such cases the larger information content of 3C BB stations has necessarily to be exploited. Also the International Monitoring System (IMS) of the CTBTO with its rather autonomous global network of a relatively limited number of high quality stations has shown great interest in the performance of 3C-station based automatic event detection, classification and location schemes (Riggelsen and Ohrnberger, 2012).

Saari (1981) described an algorithm for automatic event location by using single-site, 3C seismograms from near earthquakes ( $D < 100$  km) and Cichowicz (1993) an automatic S-wave picker. Earle and Shearer (1994) extended the STA/LTA trigger concept to 3C broadband velocity records and their bandpass-filtered versions in all distance ranges. Astiz et al. (1996) additionally used axes rotated records from the NEIC data base and the Global Seismic Network (GSN) in order to take into account also the different polarization properties of the various seismic phases that appear in different frequency bands and distances ranges. These authors took the STA/LTA along an envelope function generated from the seismogram, thus adapting the trigger parameters to the variable amplitude-frequency content of seismic noise and signal in the band-pass filtered records. The algorithm returns arrival times and related pick qualities which can then be associated in plots of travel-time versus distance easily with theoretically expected travel-time curves. Some of the travel-time-period-polarization-distance plots of these authors have been reproduced as Figs. 2.57, 2.58 and 2.61, together with the related IASP91 theoretical travel-time curve for short-period and long-period phases in Figs. 2.59 and 2.60.

With this automatic procedure it has been possible to pick practically all seismic phases which could be expected according to the 1D global travel-time model and which an experienced analyst would be able to recognize and identify with different relative frequency according to their different average SNR in seismic records of different type and in different components (see, e.g., Fig. 11.16). Picks made from LP records are less precise but good enough to reveal the discrepancy in SV and SH travel-times due to upper mantle anisotropy, being larger for SS than for S. Moreover, the travel-time residuals from the short-period automatic picks were comparable with those reported to the ISC from mostly human analysis. This indicates that human picking errors are not the main reason for the observed data scatter but rather travel-time inhomogeneities due to local site effects and velocity heterogeneities along the travel paths as compared to the 1D Earth model used in the computations.

Trabant et al., (2012) developed the Astiz et al. (1996) procedure further for real-time applications to all events with magnitude  $\geq 6.0$ . Their “Global Body-Wave Envelope Stacks”

are generated by stacking of envelope functions in  $1^\circ$ -distance bins. The envelopes have the mean pre-P-wave noise removed, and the square roots of the amplitudes are then summed. The stacks are nonlinearly weighted by the number of contributing seismograms to enhance visualization of the wave field. They are among the about 70 different automatically generated “Event Plots” published by the IRIS Data Management Center (DMC) about 2 hours after origin time, including, amongst others, also global surface- and body-wave record sections, virtual array P-waves and vespagrams and P-wave coda stacks (see <http://www.iris.edu/spud/eventplot>). An example of a body-wave envelope stack plot for the 2013 Mw(GCMT)8.3 deep Sea of Okhotsk earthquake is given in Fig. 11.83.

**Fig. 11.83** IRIS DMC global body-wave envelope stacks for the May 24, 2013, Mw(GCMT)8.3 Sea of Okhotsk deep earthquake ( $h = 598$  km) with inserted station distribution map and superposed theoretical AK 135 body-wave travel-time curves. Courtesy of A. Hutko, 2014.

For the same event we presented in Fig. 11.15 an unfiltered STS2 broadband record of the German station RUE at  $D = 67.9^\circ$ . However, for the envelop travel-time stack a 0.1-0.5 Hz bandpass filter had been applied, as compared to the unfiltered 0.0083-20 Hz STS2 record in Fig. 11.15. Therefore, in the DMC vertical component plot the more long-period and usually also more horizontal component phases SS, sSS, as well as the inversely dispersed mantle surface waves are not present. Also the usually distinct core phases PKP, SKP and SKS are underrepresented do to the lack of stations at  $D > 100^\circ$  for this specific event (see inserted map of station distribution). In any event, such near real-time plots allow a quick assessment of data availability and quality for almost all sufficiently large and thus hazardous earthquakes. Moreover, similar to vespagrams, these plots are especially useful for quickly scanning events to determine whether in the considered bandwidth range specific phases are visible in the data or not.

Fig. 11.84 compares long-term Astiz et al. (1996) STA/LTA stacks with the respective new global IRIS stacks based on about 20-times more data. The improvement is obvious.

**Fig. 11.84** Comparison of the long-term Astiz et al. (1996) vertical component STA/LTA stacks for  $T < 6$  s with the respective new global IRIS stacks in the period range  $4.5 \text{ s} < T < 7.5 \text{ s}$ , based on more than 600,000 event records. For more and updated information see <http://www.iris.edu/dms/products/globalstacks>. Compiled by courtesy of A. Hutko, 2014.

Chapter 16 gives many more examples on automatic event detection, phase picking and phase identification based on single component, 3-component-, network and array records. Amongst these examples the authors brief also on essentials of the rather sophisticated 3C algorithms developed by Tong and Kennett (1995, 1996) and Bai and Kennett (2000). These algorithms

combine automated detection and phase association for first and later arrivals and have been implemented in an experimental expert systems for automatic later phase identification and event location by means of single station 3-component broadband records. One key element was the introduction of a complexity measure for better discrimination between seismic signals and noise. It mimics the performance of the human eye, which uses the local change in frequency as a key criterion for a phase arrival. Also polarization analysis proved to be quite successful in distinguishing body waves from background noise. Assessing the performance of this robust and near real-time automatic event-recognition and classification system for teleseismic earthquakes Tong and Kennett (1996) conclude that "...the more phases detected and identified when recognizing a seismic event, the better discrimination between the possible solutions ...". In most cases their estimated event distances were within 7% and the related azimuths within 5°, thus constraining the location within 4° caps. This compares well with what also an experienced analyst could achieve off-line with some more time delay even with simple analog 3C data analysis (section 11.2.6.2 and EX 11.2), or even better and more comfortably nowadays interactively with modern PC-assisted analysis programs (see example 6 in IS 11.6). Surely, no single station location cannot compete at all with modern seismic network locations and are not thought to be propagated here as being a viable alternative for the latter. But they illustrate what would be achieved already with competent comprehensive data analysis in near real-time with just one good 3C-BB station in the case that network locations are not timely available, for what reason ever. And for "Seismology at Schools", undergraduate geoscience courses or public demonstrations on how seismology works (concept Education and Outreach) such on-the-spot single-station performance demonstrations are much more attractive and convincing than the reference to the near real-time communication about a seismic event by the agency processing the data of an anonymous regional or global network consisting of dozens to hundreds of stations.

In a follow-up paper Bai and Kennett (2000) proposed for arrival recognition and detection of a variety of P and S type phases a combination of three different techniques with different sensitivity to noise. They may be applied with different weightings to account for specific station site effects such as temporal/seasonal variations in the nature and power of seismic noise. The authors applied this method to unfiltered records in a wide range of epicentral distances from far-regional to teleseismic. Thus they followed the precept of Douglas (1997): "...the less filtering, the better the algorithm." The procedure works successful even when noise is quite low and weak phases are buried in the coda of earlier events. For the used set of windows and thresholds they achieved an effective precision of onset-time picking of about 1 s, thus constraining the differential time between P and S to within 2 s. This corresponds to about 0.3° in the distance range between 20° and 60°. Once a phase detection has been made even more sophisticated picking algorithms may be applied subsequent filtering can help to clarify the nature of phases. such as the tensor AR method by Leonard and Kennett (1999). S

While the above approach focusses on the comprehensive picking and interpretation of later phase onsets in 3C-records at single stations VanDecar and Crosson (1990) aimed at the determination of teleseismic relative phase arrival times using multi-channel regional network records, their cross-correlation and least squares. They found for quality records of the Washington Regional Seismograph network that the rms uncertainty in arrival time estimates was of the order of the sampling interval of 0.01 s. Also the reproducibility of delay anomalies was excellent for events from the same geographic location, even if their waveform character differed significantly.

Outlining further the details of these methods would go, however, well beyond the scope of the Manual. Here the original literature needs to be consulted. The same applies to the machine learning approaches by Ohrnberger and his team (e.g., Riggelsen et al., 2007; Riggelsen and Ohrnberger (2012); Hammer et al., 2012). Therefore, we will introduce them only briefly in the next and last section.

### **11.6.3 Machine learning approaches for improving event detection and classification at single 3-component seismic stations**

Ohrnberger (2001) was the first who applied Hidden Markov Model (HMM) based speech recognition techniques to parameters deduced from the continuous analysis of seismic data recorded at the Mt. Merapi volcano (Chapter 13; also: Hidden Markov Model Toolkit HMT, <http://htk.eng.cam.ac.uk/>; Python toolbox ObsPy, <http://www.python.org/> and <http://docs.obspy.org/index.html>). Riggelsen et al. (2007) introduced the method of Dynamic Bayesian networks (DBNs) to supervised learning in seismology. One of the key elements in their detection procedures is the adaptation to drifts in the noise characteristics. This results in distinct improvement of performance.

In order to cope with the situation of sparse networks, e.g., at volcanos and in particular also during volcanic crises, Beyreuther et al. (2012) designed an earthquake detector with a probabilistic architecture. It is based on the generation of characteristic functions and the derivation of a multi-dimensional feature vector via principal component analysis and inverse weighting. It performs already well when applied to just a single station. In contrast to the analysis of teleseismic earthquake records, where the emphasis lies on the detection and identification of as many as possible phase onsets for a given event, the main task in volcano seismology is to detect and discriminate/classify different types of volcano-seismic events of different origin such as volcano-tectonic event (VT), Hybrids (HY) with characteristics of both “high-frequency” and “long-period” earthquakes, or rock falls (GU). In periods of reactivation or ongoing eruption of a volcano they may occur in dense and mixed sequences in different relative proportions. The relative frequency and strength of occurrence of these different types of events have both predictive power and assessment quality for the formulation of a likely pending volcanic threat or the objective characterization and documentation of an ongoing activity. Applying the procedure to almost 4 months of continuous data sampling during the activity period of Mt. Merapi, Indonesia, in 1998, the authors concluded that even single channel single station multi-parameter HMM triggers work well, provided that they have been well-trained with a sufficient number of representative training events for the various classes. In terms of objectivity and reproducibility of the classification results the procedure may be equivalent or even outperform those of an experienced volcanologist who bases his decisions on the waveforms recorded at many more sensors.

However, often training set data are not available and their compilation and testing is a tedious process which takes quite some time. Therefore, Hammer et al. (2012) took a HMM *learning-while-recording* approach for volcano monitoring. In a first step the algorithm converts the seismic waveforms into a sequence of n-dimensional parameter vectors. This compressed signal representation increases the robustness of the procedure. After creation of the draft model for each particular event type, the classification process can be started on an unknown data stream and begin to retrain the original classification model as more and more

data become available. Moreover, new event type classes can be created if incoming data segments cannot be associated with any of the previously specified classes. The procedure has been applied to the detection and classification of volcano-tectonic events, hybrids and rockfalls in records at Soufrière Hills volcano, Montserrat (Fig. 11.85). The initial recognition accuracy of 84% could be increased to 97% by retraining the system on newly detected events.

**Fig. 11.85** Left: Typical examples of VT, HY and GU events recorded at Soufrière Hills volcano, Montserrat. Right: Characteristics of these three considered signal classes. Compiled from Figure 6 and Table 2 in Hammer et al. (2012), BSSA, **102**(3), pp. 954 and 955; © Seismological Society of America.

The same algorithm has been applied by Hammer et al. (2013) to small earthquakes with magnitudes  $M_l < 2.5$  and source depth  $\leq 20$  km and thus record durations less than 20 s in an area of 2700 km<sup>2</sup> in Switzerland. They had to be detected and discriminated from quite many quarry blasts and rare rockfalls in records of the only seismic station, FUSIO, in this area. Over the 9 years of the Swiss Earthquake Survey (SED) event catalog analyzed for the small area under investigation with the continuously re-trained self-learning algorithm, 97% of all events (earthquakes, quarry blasts and rockfalls) have been detected and none of the earthquakes or quarry blasts been misclassified as rockfall. But there is disagreement between the automatic and human classification for about 11 % of the detected events whether these are earthquakes or explosions.

These examples give an idea of the development of theoretical concepts and procedures for automatic detection and classification of seismic events. They show, as of now, what can be achieved with them and what not. But the various discussions in this section and in Chapter 11 as a whole also reveal what still remains to be the permanent duty of well-educated and practically trained seismologists who work with compassion and zeal over many years in the field of comprehensive seismogram and event analysis. Without their expertise also the automation of seismological data analysis procedures will not progress in the right direction, may result in too many uncontrolled and by users not well understood “black box”-procedures and data products whose completeness and accuracy may not satisfy the requirements for long-term fundamental and applied seismological research.

## Acknowledgments

The authors are very grateful to A. Douglas and R. D. Adams for their careful reviews which helped to significantly improve the original draft of the first edition. Thanks go also to staff members of the Geophysical Survey of the Russian Academy of Science in Obninsk who shared in reviewing the various sections of this Chapter (Ye. A. Babkova, L. S. Čepkunas, I. P. Gabsatarova, M. B. Kolomiyez, S. G. Poygina and V. D. Theophylaktov). Many of their valuable suggestions and references to Russian experience in seismogram analysis were taken into account. Thanks go to M. Ohrnberger and his team for making their recent publications available. We are grateful also to K. Stammler, for useful information and clarifications with respect to the procedures of the SZO Hannover and the analysis program SHM as well as to B. Weber and J. Saul for the same with respect to SeisComp3. Our greatest thanks, however, go to the four reviewers of the largely new and amended Chapter 11, L. Ottemöller, D. DiGiacomo, J. Schweitzer and W. Strauch. Their comments helped greatly to clarify several issues and to streamline and shorten the first draft. W. Strauch additionally contributed the subsection on Earthworm and A. Hutko from IRIS the Figs. 11.83 and 11.84 together with related references and links.

**Note:** “G” after the depth information means that the given figure (in km) is based on the estimate by a geophysicist, “N” means that the depth was assumed to be “normal” and fixed to 33 km. If the depth is given in km it has been calculated based on (depth) phase data. D – epicentral distance in degree, BAZ – backazimuth in degree, h – source depth in km.

### Example 1: Local earthquake south of Limburg/Lahn - Germany

SZGRF-data: 2000-07-26 OT 12:19:23 50.25N 8.04E h = 10G Ml = 3.5

**Figure 1a** Short-period (Wood-Anderson = WA) filtered Z-component seismograms recorded at 12 GRSN/GRF stations (for network position and outlay see Fig. 11.3). Trace amplitudes are normalized and traces are sorted according to increasing epicentral distance from 29 km (TNS) to 447 km (GEC2).

**Figure 1b** High-pass filtered (0.7 to 4 Hz) 3-component record of the local station TNS (D = 29 km). A few minutes after the main shock 3 smaller aftershocks occur.

**Figure 1c** Three-component BB record of station TNS at  $D = 29$  km. Horizontal components are rotated in the R (radial) and T (transverse) directions. One second after  $P_g$  a converted P to S wave occurs on the T component (mark X). The sampling rate is 20Hz. Note: “Filter: None” in the uppermost line always means velocity broadband record.

**Figure 1d** Three-component BB record of station TNS. The sampling rate is 80 Hz.

**Example 2: Local earthquake in Northern Germany. Generally, this region is regarded as aseismic.**

SZGRF-Daten: 2000-05-19 OT 19:22:40.8(UTC) 53.47N 11.10E  $M_l = 3.4$

**Figure 2a** High-pass filtered (0.7 to 4 Hz) 3-component records of 7 GRSN stations. The traces have been sorted according to increasing distance ranging from  $D = 73$  km (BSEG) to 405 km (TNS).

**Figure 2b** Short-period (WA) filtered Z-component seismograms of the same earthquake as in Figure 2a. First motion polarities can be read from traces 1, 2, 5 and 6, only.

**Figure 2c** Three-component WA record at station BSEG at  $D = 73$  km and  $BAZ = 135^\circ$ . The radial component R shows in the direction of wave propagation, the transversal component T is perpendicular to R.

### Example 3: Regional earthquake south of Wien

SZGRF-data: 2000-07-11 OT 02:49:51(UTC) 48.10N 16.40E Ml = 5.2

**Figure 3a** Vertical-component BB records of 5 GRSN/GRF stations and 3 Austrian stations (ARSA, MOA, KBA). Seismogram trace amplitudes have been normalized and the traces sorted according to increasing distance (D = 100 km to ARSA is 100 km and 490 km to MOX).

**Figure 3b** Three-component BB records of the stations ARSA ( $D = 100$  km), MOA ( $D = 160$  km) and KBA ( $D = 250$  km) of the Austrian network (ZAMG Wien).

**Figure 3c** Vertical-component BB records of 5 GRSN stations with phases Pn and Pg. Traces are shifted and aligned for Pn according to a reference station (WET) at  $D = 284$  km. Recorded Pn-onsets are weak and polarity readings are impossible

**Aftershock: 2000-07-11 OT 10:56:04.5 (UTC) 48.01N 16.48E MI = 4.7**

**Figure 3d** Vertical-component BB records of 8 German GRSN/GRF-stations (WET, BRG, GRC1, GRB1, GRA1, CLL, MOX, BFO), 4 Austrian ZAMG-stations (ARSA, MOA, OBKA, DAVA) and 1 Czech GEOFON-station (MORC). Trace amplitudes have been normalized and the stations sorted according to increasing distance ( $D = 96$  km to ARSA and 920 km to BFO).

### Example 4: Earthquake in Yugoslavia

NEIC-data: 1998-09-29 OT 22:14:50 44.11N 20.04E h = 10km mb = 5.2  
(D = 8.2° and BAZ = 130° from GRA1)

**Figure 4a** Vertical-component BB records of 10 GRSN/GRF-stations sorted according to increasing distance (D = 6.45° to GEC2 and 10.0° to TNS).

**Figure 4b** Three-component BB-displacement (Kirnos filtered) record of station MOX ( $D = 8.7^\circ$ ,  $BAZ = 136^\circ$ ) with phases Pn, weak Sn and strong dispersed surface waves (LQ onset in N-E around 22:19:10 and  $LR_{max}$  in Z at 22:20:45; note onset-like Lg phases arriving between Sn and LQ).

**Figure 4c** Time-shifted and aligned vertical components BB records of the 13 GRF-array stations (see Fig. 11.3a for array position and outline). Traces are sorted according to increasing distance.

### Example 5: Earthquake in Albania

NEIC-data: 1998-09-30 OT 23:42:54 41.95N 20.39E h = 10km Ms = 5.1  
(D = 10.0° and BAZ = 137° from GRA1).

**Figure 5** Three-component BB-displacement (Kirnós filtered) record at the GRSN station WET at D = 8.9° (BAZ = 136°). Note the clear onset of Pn, a very pronounced long-period Sn (as compared to the very weak Sn in the record of the Yugoslavia earthquake in Figure 4b above) and well dispersed surface waves of dominantly Rayleigh (LR) type (because of the strong vertical component).

### Example 6: Earthquake in SOUTHERN ITALY

USGS NEIC-data: 1998-09-09 OT 11:27:58.6 39.964N 15.948E h = 10km  
mb = 5.3 Ms = 5.2

SZGRF-data: 1998-09-09 OT 11:28:01.8 40.1N 16.4E Ms = 5.2

Distance (GRA1) D = 10.3 deg, BAZ = 157 deg

**Figure 6a** Three-component BB record at the GRF-station GRA1 ( $D = 10.3^\circ$ ,  $BAZ = 159^\circ$ ) with clear phases Pn, Sn and surface waves (Lg arriving around 11:34:00 and Rg around 11:35.40).

**Figure 6b** Highpass-filtered (0.7 to 4 Hz) Z-component records with Pn onsets at 13 GRF-array stations. Traces are aligned and sorted according to increasing distance ( $D = 9.45^\circ$  to GRC3 and  $D = 10.33^\circ$  to GRA3). The coherency of Pn is poor at this distance range.

**Figure 6c** Vertical-component BB records with Pn and Sn waves from 10 GRSN-stations. The traces have been sorted according to increasing distance between  $D = 8.86^\circ$  (FUR) and  $14.5^\circ$  (BSEG). Except for stations CLL, BRG and BSEG clear Sn arrivals are visible.

| Topic       | Additional seismogram examples within the distance range 13° - 100°                                                                                                                               |
|-------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| compiled by | Klaus Klinge (formerly Federal Institute for Geosciences and Natural Resources, 30655 Hannover, Germany);<br>E-mail: <a href="mailto:klaus.klinge@googlemail.com">klaus.klinge@googlemail.com</a> |
| Version     | October, 2001; DOI: 10.2312/GFZ.NMSOP-2_DS_11.2                                                                                                                                                   |

**Note:** Most of the examples given below show either records of the German Regional Seismic Network (GRSN; aperture about 500 x 800 km) or of the Gräfenberg broadband array (GRF; aperture 45 x 110 km; see Figs. 8.14 and 9.4 in the manual Chapters 8 and 9). The following abbreviations have been used: D – epicentral distance in degree, BAZ – backazimuth in degree, h – focal depth in kilometer. Complementary comments have been added by the Editor.

### Example 1: Earthquake in Greece

USGS NEIC-data:1999-09-07 OT 11:56:50 38.13N 23.55E h = 10km mb = 5.8

**Figure 1a** Broadband vertical-component seismograms recorded at 9 GRF/GRSN stations within the distance range  $D = 13.4^\circ$  (WET) to  $18.2^\circ$  (BSEG). Traces have been sorted according to increasing distance. A complex P wave is followed by S and surface waves with longer-periods than P. Both body waves are influenced by upper mantle discontinuities. Note the large P-wave amplitude at the most distant station BSEG because amplitudes increase rapidly towards the “20° discontinuity” (see Fig. 3.13 in Chapter 3).

**Figure 1b** The same record as above, however a displacement proportional KIRNOS-filter was applied. Especially S waves are displayed better by using this filter. The network traces are not coherent.

**Figure 1c** KIRNOS-filtered seismograms of vertical-component records at the GRF-array stations sorted according to increasing epicentral distance ( $D = 13.8^\circ$  to GRC3 and  $14.6^\circ$  to GRA3). Note the variability of waveforms within the S-wave group.

**Figure 1d** KIRNOS-filtered three-component seismogram from the GRF-array station GRA1 ( $D = 14.55^\circ$ ,  $BAZ = 138^\circ$ ). The horizontal components N and E have been rotated into the radial (R) and transverse (T) direction. The onsets of the body waves P and S and of the long-period surface waves LQ (Q) and LR (R) have been marked.

**Figure 1e** Low-pass (left) and high-frequency band-pass filtered (0.5-5 Hz) seismograms of the same earthquake recorded at station KIV (Kislovodsk; Russia) at the distance  $D = 15.2^\circ$ . The horizontal components N and E have been rotated into the R and T direction. No long-period waves are visible in the high-frequency record (courtesy of Lars Ottemöller, 2002).

## Example 2: Earthquake in NW-TURKEY

USGS NEIC-data:1999-11-12 OT 16:57:20 40.79N 31.11E h = 10km  $M_w = 7.1$   
( $D = 16.5^\circ$  to GRF,  $BAZ = 115^\circ$ )

12.11.1999  $M_w 7.1$  (NEIC)

**Figure 2a** The Düzce earthquake of November 12, 1999 occurred about 110 km east of the earlier Izmit earthquake of August 17, 1999. The map shows the epicenter regions of both earthquakes together with one moment-tensor solution (for the Izmit event) and the right lateral surface displacement values (in cm) observed after the first shock.

**Figure 2b** Broadband vertical-component seismograms recorded at 12 GRSN stations. Traces are sorted according to increasing distance ( $D = 14.7^\circ$  from GEC2 and  $19.6^\circ$  from BUG). A clear P wave is followed by a relatively weak S and strong dispersed surface waves with much longer-periods than P. The P and S waveforms, influenced by upper mantle discontinuities, show a complicated structure. Note the growing P-wave complexity and amplitudes with increasing distance towards the “20° discontinuity” (see Fig. 2.29 in Chapter 2 and Fig. 3.13 in Chapter 3).

**Figure 2c** Broadband vertical-component seismogram with P-wave onsets recorded at all GRF-array stations. Traces are sorted according to increasing distance ( $D = 12.86^\circ$  from GRC3 and  $13.03^\circ$  from GRA1) and shifted in time according to a reference station (beamforming). All signal onsets are coherent. The weak first arrival of the P-wave onset is marked on the GRF-station GRA1.

**Figure 2d** Broadband seismogram with P, weak S and long-period surface waves from station GRA1 (at  $D = 13.0^\circ$ ).

### Example 3: Earthquake in Southern TURKEY

USGS QED-data: 1998-06-27 OT 13:55:49 36.95N 35.31E h = 10G Ms = 6.2  
(D = 21.6° to GRF)

**Figure 3a** Broadband seismograms with high time resolution showing the complex P-wave groups. Records were made on vertical components of 10 GRSN stations at epicentral distances between  $D = 19.7^\circ$  (GEC2) and  $24.8^\circ$  (GSH). Traces are sorted according to increasing distance. P waves on the individual traces are influenced by upper mantle discontinuities and signals are not coherent.

**Figure 3b** Broadband seismogram with P- and S-wave onsets recorded at 12 GRF-array stations. Traces are sorted according to increasing distance. P and S waves on the individual traces are influenced by upper mantle discontinuities and signals are also not coherent.

**Figure 3c** Three-component displacement-proportional KIRNOS-filtered seismogram recorded at the GRF-main-station GRA1 ( $D = 21.6^\circ$ ). The original N- and E- horizontal components have been rotated with R showing into the source direction. The time difference between the onsets SH (horizontal polarized S wave) and SV (vertical polarized S wave) is about 4 sec. The reason for this difference may be the anisotropy of upper mantle layers.

### Example 4: Earthquake in ICELAND REGION

USGS QED-data: 1998-06-04 OT 21:36:54.2 64.009N 21.294W h = 10G  
mb = 5.1 Ms = 5.1 (D = 22.5° to GRF)

**Figure 4a** Broadband vertical-component seismograms recorded at 13 GRSN stations. Traces are sorted according to increasing epicentral distance (D = 18.9° to BSEG and 24.2° to GEC2), shifted in time and aligned for better signal comparison. All signals are incoherent and influenced by upper mantle discontinuities.

**Figure 4b** Broadband vertical-component seismograms recorded at the GRF-array stations. Traces are sorted according to increasing distance (D = 22.48° to GRA3 and 23.27° to GRC3), shifted in time and aligned for better signal comparison. Because of the smaller aperture of the array as compared to the GRSN network signals are more similar. At the nearest stations (GRA3 up to GRA4) a second onset appears about 10 s after P.

**Figure 4c** Simple three-component broadband seismogram at station GRA1 ( $D = 22.5^\circ$ ) with clear P, S and surface waves. Horizontal components have been rotated (ZRT) with R into source direction.

### Example 5: Earthquake at the Afghanistan -Tajikistan border region

USGS QED-data: 1998-05-30 OT 06:22:28.7 37.050N 70.086E h = 33N  
 mb = 5.8 Ms = 6.9 ( $D = 43.5^\circ$  and BAZ =  $83.7^\circ$  from GRF)

**Figure 5a** Three-component long-period seismogram (WWSSN-LP simulation filter) recorded at station MOX ( $D = 43.2^\circ$ , BAZ =  $85^\circ$ ) with P, S and dispersed surface waves. The nuclear explosion in Pakistan (see Figure 6.2) was recorded within the coda of this strong earthquake. As compared with the earthquake no surface waves has been recorded from the nuclear explosion.

**Figure 5b** Short-period filtered P-wave onsets (WWSSN-SP simulation) recorded at 13 GRSN stations within the distance range between  $D = 41.7^\circ$  (BRG) and  $46.5^\circ$  (GSH). P-wave trains are rather complex as compared with the records of the nearby underground nuclear explosions (see DS 11.4, Figures 2 and 3).

### Example 6: Deep-focus earthquake in the HINDUKUSH REGION

USGS NEIC-data:1999-06-21 OT 17:37:29 36.40N 70.63E h = 249km  
mb = 5.7 (D = 44.3° to GRF, BAZ = 84.1 deg)

**Figure 6a** Short-period filtered seismogram (WWSSN-SP simulation) recorded at 12 GRSN, GRF(GRA1), GERESS and GEOFON stations. Traces are sorted according to distance (D = 42.4° to BRG and 47.6° to WLF), shifted and aligned for P onsets. Note that the travel-time curves for PcP and PP intersect in this distance range. Depth phases pP and sP (see the marked theoretically expected arrival times) are not visible on this short-period filtered record.

**Figure 6b** Stations and source parameter as in Figure 6a, however records of displacement-proportional Kirnos-simulation. Phases P, PP and the depth phases sP, sPP are clearly visible on these records while the phase pP is recognizable only at GEC2.

## Example 7: Earthquake in the Laptev Sea Region

USGS NEIC-data: 1996-06-22 OT 16:47:13.1 75.812 N 134.710 E  $h = 10G$   
 $m_b = 5.6$   $M_s = 5.5$

**Figure 7a** Vertical (Z) component short-period seismograms (WWSSN-SP simulation filter) recorded at 14 GRSN stations. Traces are sorted according to increasing epicentral distance which ranges between  $D = 44.5^\circ$  for RGN (with  $BAZ = 17.5^\circ$ ) and  $51.4^\circ$  for BFO (with  $BAZ = 14.7^\circ$ ). P, PcP and PP are clearly visible. Note the decreasing travel-time difference (PcP - P) with increasing epicentral distance and the related small slowness values ( $sl < 4$  s/deg) for the core-reflected wave PcP. At a distance of about  $45^\circ$  (see record of station RGN) the travel-time curves of PcP and PP intersect. Generally, PcP is well recorded on short-period filtered records, however no PcP onset is recognizable above the noise level in the records of stations STU, MOX and BUG.

**Figure 7b** The same records as in Figure 7a, however, traces have been time-shifted and aligned for the P onsets. This figure shows more clearly the decreasing travel-time difference ( $P_{cP} - P$ ) with increasing distance from the epicenter.

**Figure 7c** Short-period filtered seismograms recorded at the GRF-array. Traces are sorted according to increasing distance ( $D = 49.48^\circ$  to GRA3 and  $50.33^\circ$  to GRC2), shifted in time and aligned for P onsets. Phases P, PcP and PP have been marked. Because of the smaller spacing of the array-stations as compared with the GRSN stations, the decrease of the travel-time difference PcP-P is less obvious.

# **Example 8: Record of an earthquake in Mongolia**

USGS-QED-data: 1998-09-24 OT 18:53:40.2 46.274 N 106.237 E h = 33km  
mb = 5.3 Ms = 5.4, (D = 59.4° and BAZ = 54° from GRF(GRA1))

**Figure 8a** This is an example for an event with coherent short-period P waves within the GRSN (WWSSN-SP simulation filter). Additionally, the record of the GEOFON-station WLF in Luxembourg is shown on trace No.14. The traces are sorted according to increasing distance (D = 57.3° to BRG and 62.1° to WLF), shifted and aligned for P onsets. The most remarkable feature is the strong variability of the P-wave signal-amplitudes within this regional network. The table below gives the measured amplitudes together with the calculated magnitudes. Body-wave magnitudes mb vary between 5.4 (GEC2) and 6.2 (GRA1). The depth phase pP was used to estimate a better source depth (h = 44 km) than the value given in the QED (h = 33 km).

**Table 8a** Result of the seismogram analysis shown in Figure 8a. The table was printed from the GRSN databank and contains in the uppermost line source parameters like date, an event identification number (ev\_id) and the name of the analyst (KLI for Klinge). The following lines give the analyzed stations, onset times, phases, polarities, components, periods T, maximum amplitudes A, body- and/or surface-wave magnitudes mb/MS, epicentral distances D, beam-slowness b\_slo, beam\_azimuths b\_az. The lowermost part of the table contains source parameters like analysis center (SZGRF), origin time OT, latitude, longitude, average magnitude values for mb and MS, depth of the source and source region. Note the significant differences between the magnitude estimates mb from records of different network stations.

### Example 9: Earthquake in California

SZGRF-data:1999-10-16 OT 09:46:55 34.9N 115.9 W mb = 6.6 Ms = 7.9

The event happened east of Los Angeles (D = 83.6° BAZ = 319° from GRF) .

**Figure 9a** Broadband vertical-component seismograms recorded at 12 GRF-array stations. Traces are sorted according to increasing distance (D = 83.6° to GRA3 and 84.4° to GRC3), shifted in time and aligned for P onsets. The coherent phases P and PP are marked, however some more onsets appear ahead of PP.

**Figure 9b** Broadband vertical-component seismograms recorded at 13 GRSN-stations. Traces are filtered (Kirnos-simulation), sorted according to increasing distance ( $80.1^\circ$  to BSEG and  $85.3^\circ$  to GEC2), shifted in time and aligned for P onsets. The used displacement proportional broad-band filter displays clearly the coherent part of the wave train from the network. As in Figure 9a, coherent phases appear ahead of PP that have slowness values as P.

**Figure 9c** Broadband three-component seismogram recorded at GRA1 ( $D = 83.6^\circ$ ). The horizontal components are rotated into the R and T direction. Phases P, PP, S, SS and surface waves are displayed. Rayleigh waves recorded on radial and vertical components appear later than Love waves recorded on the transversal component only.

# **Example 10: Earthquake near the coast of NICARAGUA**

USGS NEIC-data: 1998-10-09 OT 11:54:29.0 11.337N 86.429W h = 10km  
mb = 5.6 Ms = 5.6 (D = 86.3° and BAZ = 282° from GRF(GRA1))

**Figure 10a** Short-period seismograms (WWSSN-SP simulation filter) from 23 broadband stations of the GRF-array, the GRSN network and the GERESS array (GEC2). Traces are time-shifted, aligned for P and sorted according to increasing distance (D = 83.1° to GSH and 88.1° to GEC2). Note the large number of onsets within the first 40 sec of the P-wave group (P, pP, X1, X2, X3, X4). The reason for these multiple onsets may be a multiple rupture process or (in some cases) reflections from the nearby subduction zone.

**Figure 10b** Long-period seismograms (WWSSN-LP simulation filter) of the same stations as in Figure 10a, depicted with high time-resolution. Traces are aligned and sorted according to increasing distance. Note the very long-period P-wave onset ( $T \approx 14$  s) in the time window between P and X2 where the P-wave amplitudes are relatively small in the short-period filtered records whereas at X4, which is by far the largest onset in Figure 10a, no long-period wave onset is to be seen. This seems to speak of an initially “slow” earthquake rupture which then escalated into a faster rupture or the break of a “harder” asperity which generated more short-period energy.

9-OCT-1998\_12:06:59.015 >45.21< Filter: SRO\_LP

LastCmd: Theo (Table

**Figure 10c** Time-compressed long-period filtered three-component seismogram (SRO-LP simulation filter) of the Nicaragua earthquake recorded at station MOX ( $D = 86.4^\circ$ ,  $BAZ = 283^\circ$ ). Horizontal components have been rotated into the R (radial) and T (transverse) direction. The seismogram shows long-period phases P, PP, SKS, SP, SS and surface waves L (or LQ for Love wave) and R (or LR for Rayleigh wave). Note the remarkably simple waveforms of P and PP as compared with the complicated structure in the short-period P-wave group in Figure 10a.

### Example 11: Earthquake in Taiwan Region

USGS NEIC-data: 1996-08-10 OT 06:23:08 24.032 N 122.550 E h = 46G  
mb = 5.2 Ms = 5.2 ( D = 87.1° and BAZ = 56.6° from BFO)

**Figure 11a** Broadband vertical-component seismograms of the Taiwan earthquake recorded at 7 GRSN-stations within the distance range  $D = 82.9^\circ$  and  $87.1^\circ$ . Only the P-wave onset is recognizable on the records. Secondary onsets such as surface reflections of the P and S wave (theoretical onset times marked on the CLZ trace) are not to be seen above the noise level.

**Figure 11b** The same event as in Figure 11a after long-period filtering (SRO-LP simulation filter). Note the pronounced onsets of PP, PPP, PPPP as well as S, SS and SSS which are marked at the record trace of station CLL ( $D = 82.9^\circ$ ). Phase identification is eased by using absolute (see overlay to Fig. 2.48) or differential theoretical travel-time curves (see Figure 4 in Exercise EX 11.2). This is essential when interpreting single station recordings. Modern seismogram analysis program can automatically mark the theoretically expected onset times of the various phases when the epicentral distance to the station and the source depth are known or assumed. When a network of stations or array is available, phase identification is supported by *vespagram* analysis as shown in the following figure.

**Figure 11c** For better phase identification a [vespagram analysis](#) (see 9.7.7 in Chapter 9) of the long-period filtered traces was made. Identified phases have been marked on their respective slowness trace S (e.g., P on trace 4 with slowness  $S = 5.0 \text{ s/}^\circ$  and PP on trace 7 with  $S = 8.0 \text{ s/}^\circ$ ). In the vespagram traces the respective phases have the largest amplitudes at their proper slowness value.

**Example 12:** Earthquake in the region of Michoacan, Mexico

USGS NEIC-data: 1997-01-11 OT 20:28:26.0 18.193 N 102.800 W h = 33G  
 mb = 6.5 Ms = 6.9 (D = 90.9° and BAZ = 299.7° from GRFO site)

**Figure 12a** Broadband vertical-component seismograms recorded at 12 GRSN-stations are shown. Traces are sorted according to increasing distance of the stations (D = 87.7° to IBBN and 92.1° to WET). P-wave onsets are marked.

**Figure 12b** Records at the same stations as in Figure 12a, however after application of a short-period WWSSN-LP simulation filter. This is necessary for amplitude and period measurements required for standardized mb body-wave magnitude determinations. Maximum double-amplitudes ( $2A$ ) and half-periods ( $T/2$ ) are marked for the first wave group. Later onsets may belong to secondary or depth phases.

**Figure 12c** Records at the same stations as in Figure 12a, however after application of a 4<sup>th</sup>-order Butterworth low-pass filter ( $f_c = 15$  s). They show the long-period energy content of the earthquake with P-wave periods of about 20s! All long-period network traces are coherent. In this case the network can be used as an array.

**Figure 12d** Broadband three-component seismogram recorded at station CLL ( $D = 91.0^\circ$ ,  $BAZ = 301^\circ$ ). Note that at teleseismic distances P waves and their multiples show up most clearly in the Z component because of the small incidence angle, decreasing with distance, and the oscillation of P waves in ray direction. The horizontal components are rotated, with R into the source direction. The radial component shows most clearly the direction of wave propagation (or toward the source; i.e., with a  $180^\circ$  ambiguity which can be resolved by taking the direction of P-wave first-motion – up or down – into account; see EX 11.2). Accordingly, in the R component all waves show up clearly which are polarized in the Z-R plane. These are, besides the primary and multiple P waves also all waves which have been converted during their propagation at discontinuities from P into S and vice versa such as PS, PPS, SP, SSP etc. but also SKP, PKS, SKS, SKKS etc. The latter had to travel at least one segment along their travel path through the Earth's outer core (K) which is liquid and transmits no S waves. S waves, however, which have been generated by mode conversion from P waves, can oscillate only in the same Z-R plane as P itself. And when a mantle S waves hits the core-mantle boundary, only their vertically polarized SV energy can partially be converted into a P wave and penetrate into the outer core while any SH energy will be totally reflected back into the mantle. This also explains, why multiple S-wave reflections such as SS, SSS, SSSS contain an increasing part of SH energy. The primary S waves, as originating from the earthquake rupture process, may contain both SV and SH energy in variable proportions, depending on the rupture orientation in space. The SH part shows up in records of the transversal (T) component. When comparing energy arrivals in the S-wave time window in the T and R components one can discriminate between S and SKS (see figure above). Note that SKS and PS are recorded also in Z, however with smaller amplitudes because of their oscillating perpendicular to the ray orientation. An unknown phase, denoted X, appears ahead of SKS in R. Surface waves are not visible because they arrive outside of the displayed time window.

For single station analysis phases can be determined with the help of (differential) travel-time curves (see Figure 2 in Exercise EX 11.2). For a station network vespagram analysis (see also Chapter 9, section 9.7.7) proves to be a much better analysis method because of the additional slowness determination. The following three figures (12e - 12g) show vespagrams of the vertical (Z), radial (R) and transverse (T) components recorded at 12 GRSN-stations. To get a better signal coherency, all traces were filtered with a 4<sup>th</sup>- order long-period low-pass filter ( $f_c = 15$  s).

**Figure 12e** The identified phases from the vertical-component vespagram are marked on the respective slowness traces where they have their largest amplitudes (e.g. P on trace 6: belonging to a slowness  $S = 5$  s/°, PP on trace 9 with  $S = 8$  s/°, SP on trace 12 with  $S = 11$  s/° and SS on trace 16 with  $S = 15$  s/°).

**Figure 12f** The identified phases from the radial-component vespagram are marked on slowness the respective slowness traces (SKSs on trace 7 with a slowness  $S = 6 \text{ s}/^\circ$ , PS on trace 12 with  $S = 11 \text{ s}/^\circ$  and SS on trace 16 with  $S = 15 \text{ s}/^\circ$ ).

**Figure 12g** The identified phases from the transverse-component vespagram are marked on their respective slowness traces (S on trace 10 corresponding to a slowness  $S = 9 \text{ s}/^\circ$ , SS on trace 15 with  $S = 14 \text{ s}/^\circ$ ). Note, by comparing the identifications in Figs. 12e to 12g that the associated slowness values might somewhat differ because the maximum amplitudes vary only slightly when changing the slowness for about  $\pm 1$  or  $2 \text{ s}/^\circ$ .

### Example 13: Earthquake near the coast of Ecuador

USGS NEIC-data: 1998-08-04 OT 18:59:18.2 0.551S 80.411W h = 19G  
mb = 6.2 Ms = 7.1 (D = 91.5° and BAZ = 270.9° from GRF(GRA1) )

**Figure 13a** Broadband vertical-component seismograms recorded at 14 GRSN stations (D = 88.4° to 93.2°). Traces are time-shifted and aligned. The different waveforms observed at different network stations are coherent in the long-period range.

**Figure 13b:** After short-period filtering (WWSSN-SP simulation) the coherency of the different station-waveforms is bad. The maximum double P-amplitudes used for mb-estimation are emphasized. Because of the variability of station amplitudes within the network individual mb-values vary between 6.0 for BFO and GEC2 and 6.7 for other stations.

**Figure 13c** Broadband records of the vertical-components at 13 GRF-array stations ( $D = 91.5^\circ$  to  $91.7^\circ$ ). Because of the much smaller aperture of the array as compared to the GRSN the signal coherence is good for all array-traces.

**Figure 13d** Even for the short-period filtered records of the GRF-array stations (WWSSN-SP simulation) the signal coherence is still good.

**Figure 13e** Three-component long-period filtered (WWSSN-LP simulation) seismogram recorded at station TNS ( $D = 89.7^\circ$ ,  $BAZ = 269^\circ$ ). Note the much larger P-wave amplitude in the E-W component as compared to the N-S component because of the source location in the west. Also note the strong secondary phases PP, S and SS. The maximum surface-wave amplitude on the vertical component is marked (L). The estimated magnitude is  $M_s = 7.2$ . This is very close to the average value determined by the USGS NEIC from data of the global seismic network ( $M_s = 7.1$ ).

**Figure 13f** Long-period filtered (WWSSN-LP simulation) vertical-component records of the Ecuador earthquake at 8 GRSN stations within the distance range  $D = 88.4^\circ$  (GSH) to  $93.2^\circ$  (BRG). The variability of the maximum surface-wave amplitudes throughout the network is less than that of short-period body-wave amplitudes (compare with Figure 13b). Accordingly,  $M_s$  estimates from individual stations are more reliable than respective  $m_b$  estimates.

**Example 14:** Earthquake in Southern Sumatra Region

USGS NEIC-data: 2000-06-04 OT 16:28:25.8 4.773 S 102.050 E h = 33G  
 mb = 6.8 Ms = 8.0 (D = 94.1° and BAZ = 92.5° from GRF)

**Figure 14a** Broadband vertical-component seismograms recorded at 16 GRSN-stations within the distance range  $D = 92.5^\circ$  to  $96.7^\circ$ . Traces are time-shifted and aligned for better comparison of the individual records. Note the good coherency of all traces. For these broadband records the network works like an array. The weak P-wave first arrival is marked on the record of station GRFO. Maximum P-wave amplitudes were recorded about half a minute later (multiple rupture event with successively larger energy release?).

**Figure 14b** Seismograms of the same earthquake recorded at the same stations as in Figure 14a after applying a long-period filter (SRO-LP simulation). Note the very high signal coherence of the long-period P-waves with periods  $T \approx 25$  s. Also the amplitudes are comparable at all stations.

**Figure 14c** For mb estimates short-period records (WWSSN-SP simulation) have to be used to measure the maximum amplitudes with periods near 1 s. The respective filtered traces for the same earthquake and stations as in Figure 14a are shown. For three stations the P wave arrivals and their maximum double-amplitudes  $2A$  have been marked. The latter differ by a factor of five for this event. This corresponds to a difference of 0.7 magnitude units!

**Figure 14d** Three-component single station record of the Sumatra earthquake at station MOX ( $D = 93.9^\circ$ ,  $BAZ = 93^\circ$ ). The short-period filtered P-wave group is shown and the maximum peak-to-peak amplitude  $2A$  is marked as in the Z component. In this display with high time resolution the complicated rupture process of this event, consisting of a series of sub-events with successively increasing energy release within the first 25 s is very obvious. This is a very important information also for more detailed research work on source processes. Therefore, also for routine data analysis a detailed reporting of the onset times, amplitudes and periods of these sub-events is strongly recommended. An example for such an analysis is given in Tab. 3.1 of Chapter 3. In the given case, the amplitude of the P-wave maximum around 16:42:06 is about 40 times larger than that of the first arrival. This corresponds to a difference of 1.6 magnitude units between the initial and the largest sub-event of this earthquake. Accordingly, instructions for mb measurements within the first five half-cycles (NOAA in the 1960s) or within the first 5 s (IMS nowadays) might dramatically underestimate not only the energy release of earthquake in general (stronger ones in particular, because mb will always saturate at values around 6.5; see Figs. 3.5 and 3.16 and related discussions in sections 3.1.2.3, 3.2.5.2, and 3.2.7 of Chapter 3). Even worse, they will particularly underestimate the high-frequency energy release which is most relevant for potential damage assessments and for these mb is principally more suited than  $M_s$  or  $M_w$  provided, that mb is determined really from the maximum amplitudes in short-period P-wave train.

**Figure 14e** Broadband (top) and long-period filtered 3-component seismograms (SRO-LP simulation; below) of the Sumatra earthquake at station MOX ( $D = 93.9^\circ$ ). The phases P, PP, S, SKSac, SP, SS and the maximum surface wave L have been marked. For better phase identification the horizontal components N and E have been rotated into the R and T directions. The S wave is seen best on the transversal component T and P, PP, SKS and SP on Z and on the radial horizontal component R, respectively. For surface-wave magnitude estimation the maximum ground displacement with a period between 18 and 22 s was measured at the marked position L from the SRO-LP filtered vertical component. Additionally, amplitudes from the horizontal components can be used for a horizontal surface-wave magnitude value.

### Example 15: VOLCANO ISLANDS REGION

USGS NEIC-Daten: 2000-03-28 OT 11:00:21.7 22.362N 143.680E h = 119D  
mb = 6.8 (D = 96.8° BAZ = 43.5° from GRF(GRA1))

**Figure 15a** Broadband vertical-component seismograms recorded at 17 GRSN-, GRF- and GEOFON-stations. Traces are sorted according to increasing distance (D = 92.4° to RGN and 99.1° BFO). The phases P, PP and the depth phases pP and pPP are recorded very well.

**Figure 15b** Long-period filtered (WWSSN-LP simulation) three-component seismogram of the Volcano Island earthquake recorded at station RUE near Berlin ( $D = 93.7^\circ$ ,  $BAZ = 45^\circ$ ). The horizontal components are rotated, with R in source direction. Phases P, pP, SP and the onset of the Rayleigh waves LR are marked on the vertical component, SKS and PS on the radial component and S, SS, SSS as well as the Love waves onset LQ on the transversal component, respectively.

| Topic   | Additional seismogram examples at distances beyond 100°                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

**Note:** Most of the examples given below show either records of the German Regional Seismic Network (GRSN; aperture about 500 x 800 km) or of the Gräfenberg broadband array (GRF; aperture 45 x 110 km; see Figs. 8.14 and 9.4 in the manual Chapters 8 and 9, respectively). The following abbreviations have been used: OT – origin time in UT (universal time), D – epicentral distance in degrees, BAZ – backazimuth in degrees, h – focal depth in kilometer.

### Example 1: Earthquake in the Chile-Bolivia border region (intermediate source depth)

**USGS NEIC-data: 2002-03-08 OT 04:56:21.7 21.6S 68.2W h = 123 km Mw = 6.5;**  
**The epicentral distances of the GRSN stations range between 97° < D < 103°.**

Figures 1 a and b show enlarged sections of the recordings made of this intermediate depth earthquake at stations of the GRSN around the beginning of the shadow zone of the Earth's core (for the full records see Fig. 11.57 left). Figure 1a depicts the first 24 minutes of the long-period recordings (SRO-LP simulation) of the horizontal R and T components whereas Figure 1 b shows the related Z-component recordings of the first 8 min (lower part) and 17 min (upper part), respectively. The following diagnostic features can be recognized:

- Pdif is by far the smallest body-wave arrival, even in the vertical component, however, its SNR is still large enough for this medium-size earthquake in LP recordings;
- SKS (here also with its depth phase sSKS) forms the first strong shear-wave arrival, necessarily in the radial (R) horizontal component, whereas S (also with its depth phase sS) is a comparably strong later shear-wave arrival, here (however not always!) with large amplitudes in the transverse (T)-component records;
- SP (and its depth phase) is also (necessarily!) strongest in the R component whereas SS is frequently (not always! see Figure 2) strongest in the long-period T component;
- SKS and SP have also well developed onsets in Z-component LP records with amplitudes comparably strong or even larger than for Pdif and PP;
- Pdif and PP may also have well developed depth phases (here sPdif and sPP, respectively) in Z-component LP records;
- the missing of the depth phases pPdif and pPP in Figure 1b is due to the different P- and S-wave radiation pattern from a shear source (see Figs. 3.25 and 3.26) and the specific rupture orientation with respect to the seismic station in the considered case; this is not a general feature, rather pP, pPP etc. are often stronger;
- PP has, when compared with Pdif, a larger R component because of its larger incidence angle; and SP a larger Z component than PS.

2002-03-28 OT 04:56:21.7 h = 123 km Chile Bolivia border region

**Figure 1a** SRO-LP filtered BB records of GRSN stations. Upper traces: R component; lower traces: T component. Note that the phases SKS and SP, as well as their depth phases, have necessarily their largest horizontal amplitudes in the R component, as the longitudinal waves Pdif and PP. In contrast, S and SS may have their largest amplitudes in the T component, depending on the primary ratio of SV/SH energy radiated by the earthquake source.

2002-03-28 OT 04:56:21.7 h = 123 km Chile Bolivia border region

**Figure 1b** Enlarged vertical (Z)-component SRO-LP filtered BB records of GRSN stations shown in Figure 1a. Upper traces: Body-wave phases up to SP; lower traces: cut-out of the first 8 minutes of the record with longitudinal phases only. Note the well developed depth phases sPdif and sPP. The theoretically expected arrival times according to the IASP91 model (Kennett and Engdahl, 1991) have been inserted in both Figure 1a and b.

## Example 2: Earthquake in the Mariana Islands region (intermediate source depth)

USGS NEIC-data: 2002-04-26 OT 16:06:06.8 13.1N 144.6E h = 85 km  $M_w = 7.1$ ;  
The epicentral distances of the GRSN stations range between  $101^\circ < D < 108^\circ$ .

The waves from this source at nearly the same distance as for the Chile-Bolivia earthquake approach the GRSN stations from nearly the opposite backazimuth (see Fig. 11.57), however, the general wave types and waveform features in different record components are nearly the same as Figure 1, with one exception: SS is best developed in the R component and there is no S wave visible in the T component, i.e., the shear-wave energy generated by this source was almost exclusively of SV type.

**Figure 2a** SRO-LP filtered BB records of GRSN stations. Upper traces: R component; lower traces: T component. Note that in these records PS has about four times larger amplitudes than SKS and all phases are not visible or rather weak in the T component.

2002-04-26 OT 16:06:06.8 h = 85 km Mariana Islands region

**Figure 2b** Enlarged cut-out of the SRO-LP filtered BB records of GRSN stations shown in Figure 2a. Upper traces: Z component; lower traces: R component. Note the well developed depth phases sPdif and sPP. The theoretically expected arrival times according to the IASP91 model (Kennett and Engdahl, 1991) have been inserted in both Figure 2a and b. Note that the amplitude ratio Z/R is larger than for Pdif than for PP because of the smaller (steeper) incidence angle of Pdif.

### Example 3: Earthquake in the Banda Sea region (intermediate source depth) with phases PKPdif, PKKPab and PKKPbc

USGS NEIC-data: 2000-03-03 OT 22:09:13.5 7.313S 128.642E h = 148 km mb = 6.4;  
(D = 113° and BAZ = 73.9° from GRF, h = 140 km)

Shown are various short-period filtered seismograms (WWSSN-SP simulation) recorded at GRSN-, GRF- and GEOFON-stations. All traces are sorted according to increasing epicentral distance within the range D = 110.8° (RUE) and 116.2° (WLF). Phases Pdif, PKiKP, PP, SP, PKKPbc and PKKPab are shown. Additionally, ray-paths and travel-time curves are presented.

**Figure 3a** Pdif (old name Pdif) is the first arrival, however, as a diffracted wave, rather small, particularly in short-period records. Only a few GRSN stations have recorded it from this event. For more clear long-period records of Pdif see Figures 4b, 6c and 7b in the next examples.

**Figure 3b** Phases PKiKP, PP and (pPP) are shown on this seismogram. PKiKP arrives about 4 min after Pdif shown in Figure 3a. Note the strong variation at PKiKP-amplitudes within the network by a factor of about 10. The onset-time of PP can not be determined exactly. The reflection point of PP is below the complex crustal structure of Tibet.

**Figure 3c** Ray paths for Pdif, PKiKP, PKKPbc and PKKPab for the considered event at a focal depth of 148 km and with an epicentral distance to station CLL of  $D = 111^\circ$ .

**Figure 3d** Travel-time curves for PKKPbc and PKKPab for a focal depth of 148 km.

**Figure 3e** Vertical component short-period seismograms starting about 10 min after the PKiKP arrival in Figure 3b. Marked are the onset times of the phases SP, PKKPbc and PKKPab. For the branching of PKKP between about  $90^\circ$  and  $125^\circ$  see Figure 9 in EX 11.3. These late secondary phases appear in short-period records only. Their ray paths are shown in Figure 3c and their travel-time curves in Figure 3d above.

### Example 4: Earthquake in Papua New Guinea

**USGS NEIC-data: 1998-07-17 OT 08:49:15 3.08S 141.76E h = 33G Ms = 7.0;  
(D =  $117.5^\circ$  and BAZ =  $58.8^\circ$  from GRA1)**

This earthquake occurred near the coast of Papua New Guinea. Tsunami waves with a height of 10 m flooded the coast and killed about 3000 people.

**Figure 4a** Long-period filtered three-component seismogram (SRO-LP simulation) recorded at station GRA1 ( $D = 117.5^\circ$ ). The horizontal components (RT) are rotated with R into the epicentral direction. Phases Pdif, PP and a strong SP are visible on the vertical component. While the phases SKS, SKKS and PS, polarized in the vertical propagation plane, are strong on the radial (R) component Sdif, SS and SSS are strong on the transverse (T) component.

**Figure 4b** Long-period filtered vertical-component seismograms (WWSSN-LP simulation) recorded at 11 GRSN- and GRF-stations. Traces are sorted according to increasing distance ( $D = 115.4^\circ$  to BRG and  $119.9^\circ$  to BFO). Long-period onsets of Pdif and PP are very clear as well as an unidentified phase X ahead of PP. The time differences between X and PP differ from station to station. Probably X results from interfering waves PKPdf and PKiKP. An answer is given in Figure 4c.

Three minutes before the Pdif onset from the earthquake in Papua New Guinea, a small P-wave onset was recorded in the seismograms of GRSN stations from an earthquake in Costa Rica. Its source parameters were:

**USGS NEIC-data: 1998-07-17 OT 08:49:01 8.59N 83.07W h = 33G mb = 5.9;  
(D = 86.3° and BAZ = 278.8° from or GRA1)**

**Figure 4c** Long-period filtered vertical-component seismograms (WWSSN-LP simulation) recorded at 11 GRF-array stations within the distance range  $D = 86.3^\circ$  to  $86.7^\circ$ . Long-period onsets of the P wave from the Costa Rica event appear first, followed by Pdif, PKP and PP from the earthquake in Papua New Guinea. The phase X from Figure 4b could be identified from the GRF-array records as being PKPdf from the Papua New Guinea earthquake with a slowness of about  $2.0 \text{ s}^\circ$ .

**Figure 4d** Short-period filtered seismograms (WWSSN-SP simulation) recorded from the Costa Rica earthquake at 11 GRSN-stations. Traces are sorted according to increasing epicentral distance ( $D = 83.1^\circ$  to GSH and  $88.0^\circ$  to GEC2). The station-network allows to separate both events by way of slowness and azimuth determination. The estimated body-wave magnitudes  $m_b$  vary for the GRSN-stations between values below 5.0 (BUG, GSH) and 5.4 for station WET.

### Example 5: Earthquake in the region of New Britain, P.N.G.

**USGS NEIC-data: 1999-05-10 20:33:02.1 5.173S 150.915E  $h = 137$ D  $m_b = 6.5$ ;  
( $D = 124^\circ$  and  $BAZ = 51^\circ$  from GRFO)**

This magnitude 6.5 earthquake, recorded at GRFO and at the GRSN-network, shows the phases  $P_{dif}$ , PKP, PP,  $S_{dif}$ , PS, SS, depth phases and – because of a focal depth of 137 km – weak surface waves. A rare example is the well recorded phase  $P'P'P'P' = PKPPKPPKPPKPP$  in Figure 3e below. The ray paths for the identified phases of this event are shown in Fig. 11.60. For animation of ray propagation and seismogram formation see CD-ROM attached to Volume 2 and complementary explanations given in IS 11.3.

**Figure 5a** Long-period filtered three-component seismogram (WWSSN-LP simulation) recorded at station GRFO ( $D = 124^\circ$ ). The length of the record is about 1 hour. Phases Pdif, PKP, strong PP, Sdif, strong PS, strong SS and – according to the large focal depth of the earthquake ( $h = 137$  km) – relatively weak surface waves are recorded.

**Figure 5b** Shown are the first 10 minutes from the seismogram in Figure 5a. The higher time resolution separates well the phases Pdif, PKPdf, pPKPdf, an unidentified phase X (25s ahead of PP), PP and the depth phases pPP and sPP.

**Figure 5c** Long-period Z-component records (WWSSN-LP simulation) at 14 GRSN-, GEOFON- and GERESS-stations within the distance range  $D = 120.1^\circ$  (RGN) to  $126.6^\circ$  (WLF). This record section was used to perform the vespagram analysis (see Figure 5d).

**Figure 5d** Vespagram analysis for vertical-components was used for slowness determination and phase identification. Phases were identified according to slowness values and travel times. The seismogram analysis program SHM allows to choose slowness steps (here in increments of  $0.5 \text{ s}^\circ$ ). The analysis yields slowness values of  $4.5 \text{ s}^\circ$  for Pdif,  $2.0 \text{ s}^\circ$  for PKPdf and pPKPdf,  $7.0 \text{ s}^\circ$  for PP and for the phase X a value that would correspond to Pdif. The ray path could not be identified.

**Figure 5e** The network records show the rare phase 4P' (PKPPKPPKPPKP) with slowness  $S = 2.5 \text{ s}^\circ$ . It arrives 79 minutes after the origin time from the opposite azimuth direction (BAZ = 239°).

### Example 6: Earthquake in the region of Solomon Islands

USGS NEIC-data: 1996-04-29 OT 14:40:41.2 6.516S 155.037E h = 44G  
 mb = 6.3 Ms = 7.5;  
 (D = 127.3 ° and BAZ = 47.5° from GRA1)

The example below presents clear Pdif onsets on long-period filtered seismograms as well as an excellent phase 4P' = P'P'P'P' = PKPPKPPKPPKP arriving about 63 min after the first onset. All records were made at the GRF-array (see Fig. 11.3).

**Figure 6a** Broadband Z-component records at the GRF array within the distance range  $D = 127.2^\circ$  to  $127.8^\circ$  which show, besides the rather long-period Pdif, also PKPdf and PP.

**Figure 6b** The same record as Figure 6a, however, a short-period filter was applied (WWSSN-SP simulation). Pdif is no longer visible above the noise level.

**Figure 6c** The same records as in Figures 6a and b, however, after applying a long-period filter (SRO-LP simulation). A distinct Pdfff appears on the record.

**Figure 6d** Short-period filtered (WWSSN-SP simulation) seismogram. The rare phase 4P' = P'P'P'P' (PKPPKPPKPPK) was clearly recorded at the GRF-array coming from opposite direction (BAZ = 226 and S = 2.56 s/°) about 63 min after the first P onset. Trace No.12 (the sum of all traces = BEAM) shows the best signal-noise-ratio.

## Example 7: Earthquake in Santa Cruz Island

USGS NEIC-data: 1998-07-16 OT 11:56:36 11.1S 165.9E h = 110G;  
(D = 136.2° and BAZ = 37.3° from GRA1).

**Figure 7a** Vertical-component velocity BB seismograms recorded at the GRF-array (distance range between 136.1 and 136.8°). Note the very weak Pdif. The depth phases of PKPdf and PP correspond to a depth of 110 km.

**Figure 7b** The same record as in Figure 7a, however, after long-period filtering (WWSSN-LP simulation). Note the pronounced onsets Pdif and pPdif. Also remarkable is the long-period and slowly emerging onset 24 sec before PKP.

### Example 8: Earthquake in the region of Fiji Islands

**USGS-QED-data: 1994-09-30 OT 19:30:06.9 21.102S 179.204W h = 500km(G), mb = 5.1;**

The example shows pronounced core phases in the distance range 148°-152°. Short-period P waves reappear in this distance range but with discontinuous travel-time branches. In the region of the caustic, i.e. around 144°, the whole energy of direct longitudinal core phases is concentrated thus forming a strong PKP onset. Its amplitudes are comparable with that of P waves at much shorter distances (D around 50°). At distances beyond the caustic point PKP onsets are separated into individual PKP branches. The energy distribution changes with increasing distance. PKPbc (or PKP1) is the dominant branch just beyond the caustic, up to about 153°. In records of weaker events, PKPbc is often the first visible onset since PKPdf (or PKIKP), preceding PKPbc, is too weak to be observed. With increasing distance near 160° PKPbc vanishes from the record and PKPab (or PKP2) dominates the seismogram. For more details see sub-section 11.5.2.4.

30-SEP-1994\_19:48:50.219 >0.40< Filter: G\_WWSSN\_SP

**Figure 8a** Short-period filtered three-component seismogram (WWSSN-SP simulation) recorded at the broadband station CLL at an epicentral distance of  $D = 148.4^\circ$  ( $BAZ = 22^\circ$ ). Phases PKPdf, PKPbc and PKPab are easy to analyse in this distance range. Travel-time curves for the different branches of these core phases allow to determine the epicentral distance from records of a single station only with an error less than  $2^\circ$ . Note the relatively very small amplitudes on the horizontal components because of the very small (steep) incidence angle at this large distance.

**Figure 8b** Vertical-component record of station CLL, displayed with higher magnification.

**Figure 8c** Short-period filtered seismograms (WWSSN-SP simulation) recorded at 9 GRSN-stations. All traces are time-shifted and aligned for PKPdf and sorted according to increasing distance. The epicentral distance for CLL is  $148.4^\circ$  and for the most distant station BFO  $152.2^\circ$ .

### Example 9: Deep earthquake in the region of Fiji Islands

**USGS NEIC-data: 2000-12-18 OT 01:19:21.6 21.18S 179.12W h = 628 km mb = 6.4;**  
**The epicentral distances of the GRSN stations range between  $146^\circ < D < 153^\circ$ .**

Shown are enlarged cut-outs of the the PKP-wave group from the seismograms presented in Fig. 11.64. The PKP-wave group consists between  $146^\circ < D < 156^\circ (160^\circ)$  of three distinct wave arrivals PKPab, bc and df. Fig. 11.59 shows the respective travel-time curves. The figures below demonstrate the effect of the record filter on the discrimination of these closely spaced wave arrivals and the possibility to pick their onset times. The longer the center period of applied narrowband band-pass filters, the worse is the discrimination and onset-time picking for these three core-phase arrivals. Therefore, PKP phases are best picked in SP records, however, the later phases PP and PPP from so distant earthquakes are usually recognizable only in LP or BB records.

2000-12-18 OT 01:19:21.6 h = 628 km Fiji Islands region

Z-component, SRO-LP

**Figure 9a** Z component long-period (SRO-LP simulated) records of longitudinal wave groups from a deep ( $h = 628$  km) Fiji Islands earthquake at stations of the GRSN. Note the strong onsets of the depth phases sPKPdf and sPP prior to onsets PP and PPP, respectively, which follow closely.

**Figure 9b** Enlarged cut-outs of the PKP-wave group as recorded in WWSSN-SP (upper traces) and SRO-LP filtered seismograms of the GRSN stations. Note that for all three core phases the theoretically expected onset times according to the IASP91 travel-time model are about 2 s too early.

# 2000-12-18 OT 01:19:21.6 h = 628 km Fiji Islands region

**Figure 9c** Enlarged cut-outs of the PKP-wave group of the deep Fiji Islands earthquake of 18 December 2000 recorded at stations of the GRSN. Shown are, from top to bottom, the bandpass filtered BB records of two octaves bandwidth with center periods around 1s, 2s, 4s and 8 s. For center periods larger than 3s the separation of the different PKP-wave arrivals and recognition of their onset times becomes less and less clear. Note that according to the IASP91 travel-time model the three core phases should arrive about three seconds earlier.

| Topic       | Record examples of underground nuclear explosions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

## 1 Introduction

Nuclear explosions and in particular underground nuclear explosions had a dramatic influence on the development of modern seismology. All nuclear explosions are sources of elastic waves travelling over long distances in the Earth's atmosphere, in the Earth's oceans, and through the solid Earth, depending on the medium in which the explosion was conducted. These side effects of such explosions are well known and were used since the beginning of the nuclear age as tools to monitor the nuclear testing activity of foreign states (for details about today's monitoring activities see Chapter 17).

The development of seismic arrays (see Chapter 9), the homogenization of seismic instrumentation and the installation of global networks since the 1960s were triggered and financially supported by the wish to globally monitor test activities of nuclear underground explosions. Theoretical seismology has strongly benefited by the demand for more knowledge about the propagation and the attenuation of seismic waves in order to understand the differences between natural and artificial seismic sources.

Data from nuclear tests have been an important data source for numerous studies to investigate the 1D and 3D structure of the Earth's interior. Since, in contrast to earthquakes, the exact location and shot time of these explosions are often precisely known, they are very useful tools to investigate the structure of the Earth with elastic waves (see Ground Truth events in IS 8.6). Already the first test of a nuclear device had been used to investigate the crustal structure (Gutenberg, 1946) and since then the number of published studies using nuclear test observations to study in particular the P-wave velocity structure within the Earth is enormous.

Underground nuclear explosions (UNEs) are usually tests of nuclear weapon devices and performed at (known) test sites. However, some explosions were made outside of these recognized test sites for making cavities, moving large ground masses to redirect rivers or for conducting long-range seismic profiles. These underground explosions are per definition called Peaceful Nuclear Explosions (PNEs). Source information and waveform data from UNEs and PNEs can be retrieved from the open DTRA (<http://www.rdss.info/> and there go to Research Databases / Nuclear Explosions).

Thankfully, underground nuclear explosion activity has decreased in the last decades, but we think it is important to document some typical features of nuclear underground explosions as recorded at seismic stations.

## 2 Record examples of underground nuclear explosions between 1978 and 1993 within the teleseismic distance range

Below, seismic records of underground nuclear explosions (UNEs) at 5 weapon test sites and from a peaceful nuclear explosion (PNE) are shown. All records were made in the teleseismic distance range  $D > 30^\circ$  by vertical-component seismographs at station GRA1 of the Gräfenberg broadband array in Germany. The original BB records were filtered in the short-period range (WWSSN-SP simulation filter). The time scale is given below the records. The amplitudes have been normalized and the records are presented in Figure 1 in the following order:

| No. | Date       | Time        | Latitude [deg] | Longitude [deg] | Depth [km] | $m_b$ | Location (Code Name)         | D [deg] | Reference              |
|-----|------------|-------------|----------------|-----------------|------------|-------|------------------------------|---------|------------------------|
| 1   | 1988-12-17 | 04:18:09.2  | 49.879         | 78.924          | 0          | 5.9   | Semipalatinsk                | 42.34   | UK AWE (1990)          |
| 2   | 1993-10-05 | 01:59:56.68 | 41.6322        | 88.6886         | 0          | 5.9   | Lop Nor                      | 52.49   | ISC (2001)             |
| 3   | 1988-12-04 | 05:19:53.3  | 73.3660        | 55.0010         | 0          | 5.9   | Novaya Zemlya                | 30.32   | Richards (2000)        |
| 4   | 1988-10-13 | 14:00:00.08 | 37.0890        | -116.0493       | 0          | 5.9   | Nevada Test Site (Dalhart)   | 81.83   | ISC (2001)             |
| 5   | 1987-11-19 | 16:31:00.2  | -21.845        | -138.941        | 0          | 5.7   | Mururoa                      | 143.58  | UK AWE (1993)          |
| 6   | 1978-10-08 | 00:00:00.0  | 61.55          | 112.85          | 1.545      | 5.2   | PNE, USSR / Siberia (Vyatka) | 52.78   | Sultanov et al. (1999) |

D is the distance to the reference site of the Gräfenberg Array GRA1. The estimated yields for these explosions range between approximately 20 and 150 kt TNT for the weapon tests and is about 15 kt TNT for the PNE (No. 6).

With the exception of the Mururoa test all other records show a clear positive (compressional) first arrival. This is what one expects from an explosion source at all distances and azimuths if sufficient recording bandwidth and signal-to-noise ratio (SNR) is provided (see Chapter 4, Figs. 4.9 ??? and 4.10 ??? and Figures 2 and 3 below). For the Mururoa test the waveforms are influenced by the PKP caustic (Hilbert Transformation of the signal!) in the distance range around  $D = 145^\circ$  (see Chapter 2, section 2.5.4.3 ??, Figs. 2.34 and 2.35 ??) and therefore the onset polarity cannot be read reliably. Note the remarkable differences in P waveforms, which are rather short and simple for events No. 1, 2, 5 and 6 but much more complex and longer for events No. 3 and 4. This is mainly due to the specific geology and/or complex topography at the test sites in Nevada and on Novaya Zemlya. Additionally, for event No. 3, we observe also later P energy, about 5 s after the first onset, at an epicentral distance of about  $30^\circ$  due to the seismic energy refracted, reflected and scattered in the upper mantle (see Figure 4 and Chapter 2, Fig. 2.29 ??) and for event No. 5 the distinguished onsets, about 5 and 10 s after the first onset are later PKP-type onsets (see Schlittenhardt, 1996).

**Figure 1** Short-period filtered seismograms (WWSSN-SP simulation filter) recorded at station GRA1 of the Gräfenberg broadband array in Germany from underground nuclear explosions in six different areas. For source parameters and distances to GRA1 see the list above.

### 3 Records of the nuclear-weapon tests of India and Pakistan

Figures 2 and 3 show vertical component records of broadband stations of the German Regional Seismography Network (GRSN) from the underground nuclear weapons tests of India and Pakistan in 1998. All records were filtered narrowband in the short-period range around 1 Hz and sorted according to the epicentral distance. The source parameters are:

India: 1998-11-05, 10:13:44.2, 27.0780°N, 71.7190°E, depth 0 km, mb 5.2 (Barker et al., 1999) with epicentral distance and backazimuth from GRFO:  $D = 50.99^\circ$  and  $BAZ = 92.94^\circ$ .

Pakistan: 1998-05-30, 06:54:54.87, 28.4434°N, 63.7375°E, depth 0 km; mb 4.7 (ISC, 2001) with epicentral distance and backazimuth from GRFO:  $D = 44.91^\circ$  and  $BAZ = 98.12^\circ$ .

The P-wave onsets are generally simple. However, they are masked by noise at the more noisy stations. Surface-wave amplitudes were very weak and could not be analyzed at this large distance.

**Figure 2** Records of the Indian underground nuclear test on 11 May 1998. For source parameters see above. The broadband records were filtered with the WWSSN-SP response. Typical for explosions are the compressional first onset polarities at stations with high SNR.

**Figure 3** Records of the Pakistani underground nuclear test of 30 May 1998. For source parameters see above. The relatively small amplitudes of this 0.5 magnitude units smaller explosion are disturbed by high noise levels at the stations and the energy of an aftershock sequence of an earthquake in the Afghanistan-Tajikistan border region (see, e.g., Kværna et al., 2002). Therefore, the broadband records were bandpass filtered between 0.8 and 1.2 Hz, which has a narrower (about 0.5 octaves) bandwidth than the standard WWSSN-SP filter (about 1 octave) used for the Indian explosion (Fig. 2). It results in a better visibility of the signal (higher SNR). However, the signal onset is so emergent that it is not possible to read reliable first motion polarities. Note the apparently negative first onsets at stations BRG and MOX! For related discussions see section 4.2 in Chapter 4 of this Manual.

#### 4 Records of underground nuclear explosions at regional distances ( $7^\circ < D \leq 30^\circ$ )

At shorter distances ( $D \leq 30^\circ$ ) records from underground nuclear explosions (UNEs) still contain a rather large amount of high-frequency energy. This is mainly due to the difference in the source process as compared to an earthquakes (see Fig. 3.5 ??? in Chapter 3 and the related discussions in Section 3.1.1.3 ?? of this Manual). Two examples are shown below.

#### 4.1 UNE at the Northern Novaya Zemlya Test Site

Source data: 1990-10-24, 14:57:58.5, 73.3310°N, 54.7570°E, depth 0 km, mb 5.7 (Richards, 2000). The distances to the recording stations shown in Fig. 4 are: D = 9.99° (ARCES), 15.98° (FINES), 20.41° (NORES) and 30.40° (GERES).

**Figure 4** Records of the key stations ARA0, FIA0, NRA0 and GEC2 of the small aperture short-period arrays ARCES, FINES, NORES and GERES from the Novaya Zemlya test of 24 October 1990. These arrays are specialized for regional signals and ARCES, FINES and GERES are part of the International Monitoring System (IMS) under the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) in Vienna (see Chapter 17). Shown are the vertical component records a) unfiltered, b) band-pass filtered between 0.5 and 3 Hz, and c) band-pass filtered between 4 and 8 Hz. Note the relatively strong high-frequency energy that is well developed in the P-wave group up to a distance of  $\sim 30^\circ$  but no longer visible above the level of signal coda for S waves beyond  $10^\circ$  distance. S waves are stronger attenuated than P waves. At GEC2 the core reflection PcP is nicely visible and the P-wave coda is dominated by energy refracted, reflected and scattered in the upper mantle. Each trace is normalized by its maximum amplitude, which is given in digital counts together with the channel name. The time axis is labeled at each minute after 15:00:00 with 10 s between two ticks.

## 4.2 UNE of India in 1998

In Figure 2 we showed data of the Indian UNE of 5 May 1998 as it was observed in Europe. This event could also be observed at regional distances, e.g., at the Pakistani station NIL (Figure 5).

**Figure 5** Z-R-T rotated three-component record at the IRIS/IDA station NIL, Pakistan. The epicentral distance to the Indian test site is about 740 km; the amplitudes are normalized by the largest signal, which is given in counts at each channel name; shown are unfiltered data. Note the strong P- but weak S-wave arrivals. The time axis is labelled for each minute after 10:14:00 with 10 s between two ticks.

## 1 Aim

This is a tutorial with related exercise. It aims at making you familiar with the basic “circle and chord” method used for determining the epicenter of near seismic sources when a “flat Earth” approach is appropriate. The method is applied both to sources inside and outside of the recording networks. With respect to phase names and essential phase features one should also consult section 2.6.1 in Chapter 2 and record examples in DS 11.2.

## 2 Data

- Available are two sections of vertical component short-period records of stations of the former Potsdam seismic network from a local earthquake inside the network (see Figure 2) and a strong rock-burst in a mine located outside of the network (see Figure 3).
- Travel-time curves of the main crustal phases Pn, Pg, Sn, Sg and Lg from a near surface source up to an epicentral distance of 400 km (see Figure 4). These curves are reasonably good average curves for Central Europe. For any stations in this exercise at distances beyond 400 km, you may linearly extrapolate the curve without much error.
- Map with the positions of the recording stations and a distance scale (see Figure 5).

## 3 Procedure

- Identify the seismic phases in short-period records of near seismic sources.
- By means of a local travel-time curve for near-surface events determine the source distance **d** from the best fit with the identified seismic phases.
- If no local travel-time curves are available, a first rough estimate of the hypocenter distance **d** or of the epicentral distance **D** (both in km) may be found using the following “rules-of-thumb”:

$$\mathbf{d} \approx \mathbf{t}(\mathbf{Sg} - \mathbf{Pg}) \times 8 \quad \text{or} \quad (1)$$

$$\mathbf{D} \approx \mathbf{t}(\mathbf{Sn} - \mathbf{Pn}) \times 10 \quad (2)$$

with  $t$  as the travel-time difference in seconds between the respective seismic phases. These rules are approximations for a single layer crust with an average Pg-wave velocity of 5.9 km/s, a sub-Moho velocity of about 8 km/s and a velocity ratio  $v_s/v_p = \sqrt{3}$ . If in your area of study the respective average P- and S-wave crustal velocities  $v_p$  and  $v_s$  deviate significantly from these assumptions you may calculate  $d$  more accurately from the relationship:

$$d = t(S_g - P_g) (v_p v_s)/(v_p - v_s). \quad (3)$$

- Draw circles with a compass around each station  $S_i$ , which is marked on a distance-true map projection, with the radius  $d_i$  determined from the records of each station.
- The circles will usually cross at two points, not one point (the thought epicenter) thus forming an area of overlap (see Figure 1, shaded area) within which the epicenter most probably lies.
- Usually, it is assumed, that the best estimate of the epicenter position is the “center of gravity” of this shaded area of overlap. The best estimate of the epicenter is found by drawing so-called “chords”, i.e., straight lines connecting the two crossing points of each pair of circles. The crossing point (or smaller area of overlap) of the chords should be the best estimate of the epicenter (see Figure 1).

$$d \approx t(S_g - P_g) \times 8$$

$$\text{or } d \approx t(S_n - P_n) \times 10$$

**Figure 1** Principle of epicenter estimation by using the “circle and chord” method.  $S$  – station sites,  $d$  – hypocentral distance of the event determined for each station according to travel-time curves (as given in the Figure 4) or the “rules-of-thumb” (as Equations (1) and (2)).

#### Notes:

- 1) In the absence of independent information on the source depth and depth-dependent travel-times the distance  $d$  determined as outlined above is not the epicenter but the *hypocenter distance*. Therefore, for sources at depth the circles will necessarily overshoot, the more so the deeper the focus. Iterative reduction of the overshoot permits to estimate the source depth (see section 7 with linked movie).
- 2) However, even for a surface source, an ideal crossing of circles at a single point would require that all phases have been properly identified, their onset times been picked without error and that the travel-time curves/model for the given area (including the

effects of lateral variations) are exactly known and taken into account. This, however, is rarely the case. Therefore, do not expect your circles to cross all at one point.

- 3) Yet, despite note 2, the circles should at least come close to each other in some area, overlapping or not, within about 10 to 20 km, if the epicenter is expected to lie within the network and the hypocenter within the crust. If not, one should check again the phase interpretation and resulting distance estimates and also compare for all stations the consistency of related estimates of origin time (see tasks below). Any obvious outliers should be re-evaluated.
- 4) For seismic sources outside the network the circle crossing will be worse, the error in epicenter estimation larger, particularly in the direction perpendicular to the azimuth of the connection line (great circle) between the network center and the source. However, the distance control, based on travel-time differences S-P, is better than the azimuth control. Azimuth estimates are more reliable if the source is surrounded by stations on at least three sides, i.e., with a maximum azimuthal gap less than  $180^\circ$ .
- 5) With only two stations one gets two possible solutions for the three unknowns (epicenter coordinates  $\lambda$  and  $\phi$  and origin time OT) unless the source direction can be independently determined from polarity readings in three-component records of each station (see EX 11.2). If more than 3 stations are available, the estimates of both epicenter and hypocenter will improve.

## 4 Tasks, data and approaches

### 4.1 Phase identification and travel-time fit (consult also section 5 for guidance)

- Identify the main local phases Pn, Pg, Sn and/or Sg/Lg in the records of the Potsdam seismic network (Figures 2 and 3) by using the travel-time curves given in Figure 4.
- Use plots of the t-D travel-time curves on transparent sheet and of the record section on paper with identical time resolution (e.g., 1 mm/s, as for the originally analog records). Overlay the t-D curves on the records so that the D(km) axis is strictly perpendicular and the t(s) axis parallel to the record trace zero lines!
- Move the t(s) axis over a given station record trace until you find a best fit for the first arrival and onsets of several later wave groups characterized by significant change/increase in amplitude and/or period. Mark with pencil the best fitting onset times with dots on the record together with their (assumed) phase names.

#### Notes:

- 1) When searching for the best fit remember that the beginning of the later wave group with the largest amplitudes in the record is usually the onset of Sg, whereas in the early parts of the record it is Pg that is usually the largest wave. For distances  $< 400$  km Pn is usually much smaller than Pg, although for deeper crustal earthquakes with appropriate rupture orientation and for distances  $> 400$  km Pn may become strong or even the dominating P-wave amplitude (see Figs. 11.44 to 11.46 in Chapter 11 and several network record sections in DS 11.1).
- 2) From the onset-time differences Sg-Pg and/or Sn-Pn you may roughly estimate the distance of the event by using the “rules-of-thumb” (Equations (1) to (3) above). If your rough estimate from S-P is  $d < 150$  km then the first arrival should never be interpreted as Pn but rather as Pg (unless it is a deeper crustal event or the crust is less than 30 km thick). If  $d > 150$  km, try to get the best fit to the onsets by assuming that

the first arrival is Pn, however remember that its amplitude is usually smaller than that of the following stronger Pg for  $d < 400$  km.

- 3) The above said is true for near-surface events in a single-layer crust with average P-wave velocity of 5.9 km/s and sub-Moho velocity of 8 km/s. The **cross-over distance**  $x_{co}$  beyond which Pn becomes the first arrival is then approximately  $x_{co} \approx 5 z_m$  with  $z_m$  as the Moho depth. In the case of different average crustal and sub-Moho P-wave velocities,  $\bar{v}_c$  and  $v_m$ , you may use the relation  $x_{co} = 2 z_m \{ (v_m + \bar{v}_c) / (v_m - \bar{v}_c) \}^{1/2}$  to calculate the cross-over distance of Pn. However, be aware that for deeper crustal events Pn may over-take already at smaller distances!

#### 4.2 Estimation of distance and origin time (consult also section 5 for guidance)

- Write down on the record plots for each station, next to the identified main wave onsets, its assumed phase name as well as the hypocentral distance corresponding to your S-P time reading, respectively the best travel-time fit. Mark on each record the estimated origin time, which is the time of the D-axis position on the record for your best phase travel-time fit.
- Check, whether your marks for the estimated origin times on the different records are roughly the same (in vertical line) for all stations. This is a good check of the accuracy and reproducibility of your phase identifications and estimated distances. For any “outliers” check the phase identification and distance estimate again until you get agreement between the origin times within about  $\pm 3$ s.
- Compare your best estimate of origin time OT (average of all origin times estimated from the records of each station) with the OT computer solution given in the head lines of Figures 2 and 3.
- If your average OT deviates by more than about 3 s from the computer solution reconsider your interpretation.

#### 4.3 Epicenter location

- Take a compass and draw circles around each station position (see Figure 5) with the radius  $d_i$  in km as determined for the distance of the source from the station  $S_i$ . Use the distance scale given on the station map.
- Connect the crossing points of each pair of circles by chords. Estimate the coordinates  $\lambda$  and  $\phi$  (in decimal units of degree) from the chord crossings.
- Compare your coordinates with the ones given in the headlines of Figures 2 and 3. If your solutions deviate by more than  $0.2^\circ$  for the earthquake within the network and by more than  $0.4^\circ$  for the mining rock-burst outside the network, reconsider your phase interpretation, distance estimates and circle-drawings.
- Compare your solutions for phase interpretations, station distances, circle plots and estimated epicenter positions with the solutions derived by the authors when applying the same procedure (see section 6).

**Figure 2** Recordings of a near earthquake situated within the seismic network of stations shown in Figure 5. The record time scale in hh:mm:ss is given below. Note that the second strong onset in the record of station MOX has a shape and frequency that strongly differs from all other records. It is not a natural wave onset but a malfunction of the seismograph, which responds to the strong Sg onset with its own impulse eigen response and then stops recording.

**Figure 3** Recordings at regional distances from a strong mining rock-burst situated outside the seismic network of stations shown in Figure 5. Time and minute intervall are given on the abszissa.

**Figure 4** Travel-time curves for the main phases observed in records of near-surface local and near regional seismic sources. They are good average curves for Central Europe with a crustal thickness of about 30 km.

**Figure 5** Map of parts of Central Europe with codes and positions (circles) of the seismic stations that recorded the seismograms shown in Figures 2 and 3 (on the map projection all distances are true).

## 5 Some additional guidance

### 5.1 Phase identification and distance estimates by matching a seismic record with travel-time curves or using the S-P time difference

Figure 6 illustrates the identification of seismic phases in a record of a shallow local event by stepwise improved matching of recognizable (although sometimes small) wave onsets with travel-time curves and the estimation of the epicentral distance  $D$  (when source depth is assumed to be zero) from the best-fitting match.

**Figure 6** Stepwise movement of a seismic record over a local travel-time curve until a best fit for three recognizable onsets and the Lg wave group is achieved at a distance  $D \approx 327$  km. For discussion, see text.

At the first two positions we related only the first clear record onset in the early part of the seismogram with the first P-wave travel-time curve. This would be the Pg curve at 60 km distance, respectively the Pn curve at 200 km distance. But then there is no match of the onset of the largest wave group in the later part of the record with any of the well established travel-time curves. Thus, for a better match one has to move the record further to larger distances. However, as outlined above, at distances about 5 times crustal thickness, Pn is expected to arrive as the first P phase, although (at distances  $< 400$  km) with usually much smaller amplitudes than that of Pg. Therefore, we may hypothesize that the small onset marked with ?  $\rightarrow$  in the second position maybe Pn. Although its SNR  $< 2$ , its waveform differs clearly from that of the preceding noise). Indeed, with this assumption one gets a good fit for Pn, Pg and Sg, as well as the following Lg-wave maximum, at position 3. The distance read at this position is  $D \approx 327$  km.

When considering that at distances  $< 400$  km Pg and Sg are usually the two most distinct first arrivals in the earlier and later part of the record one would already get - according to Equation (1) - for the record in Figure 5 with  $t(\text{Sg-Pg}) \approx 40$  s a distance of  $\approx 320$  km. This is already a good first estimate and requires to search for a possible Pn arrival prior to Pg. If, however, in records made under normal crustal conditions,  $t(\text{Sg-Pg}) < 18$  s then one can be

rather sure that these have all been recorded at distances  $d < \approx 140$  km. No other phases can then be expected to be first arrivals in the P- and S-wave groups in this near distance range.

Figures 7 and 8 illustrate for the two seismic events to be located by the same small network these two situations. Distance estimates are made only with the rule-of-thumb (1). On such a record section the first distance estimate should be made only from a record with undoubtedly clear onsets of Pg and Sg. Deducting from the onset-time of Pg its travel-time according to the t-D curve in Figure 6 for the determined distance one gets a first estimate of the origin-time OT. It should be marked on the record trace by a bar. The line along this bar and perpendicular to all other record traces then guides fairly well phase identification, OT and distance estimates on the other station records. Just place the D axis of the travel-time curves, corresponding to  $t = 0$  from a surface source, on/respectively close to this first OT reference line and move the t-D diagram up and down until you get a best fit also with the most distinct phase onsets in the other records. Mark also their respective OT estimates. They may differ from the first one within a few seconds due to reading errors, worse SNR and/or significant lateral velocity differences.

**Figure 7** Section of records from a local seismic event in the Pg-Sg distance range. Note the marking of the first origin time OT prior to the clearest Pg at distance of 112 km. This guides also phase identification and d estimates at the other stations when using the t-D curve in Figure 6. Note the distinct wave group between Pg and Sg in records of BRGNZ, TIENZ and ALTNZ. This is not generally present and not explained by the simple travel-time model of Figure 6. Travel-time modeling for an average crustal model makes it likely that this is an SmP wave, i.e., an S-to-P conversion at an overcritical reflection angle from the Moho.

In contrast to Figure 7, Figure 8 shows a record section from another event outside of the network. All stations were at distances larger than 140 km when Pn is already the first arrival. This is easily found out by a quick check of the time differences  $t(S-P)$  between the two most distinct phases, Pg and Sg, which is everywhere  $> 18$  s. The follow-up procedure of more detailed phase identification and d determination by moving the travel-time curve of Figure 6 over the records along the first OT line estimate is the same as described above. For more

record examples in the local and regional distance range see section 11.5.1 in Chapter 11 and DS 11.1.

Digital records now permit to stretch the time and amplitude scales at will. This may significantly ease phase identification and allows much more accurate picking of onset times (see IS 11.4).

**Figure 8** Section of records from a seismic event in the Pn distance range. Note the rather vague onsets of Pg and Sg in the lower three record traces. They will allow only rough estimates of  $d$ .

## Solutions

**Figure 9** OTs, identified phases and calculated distances for a seismic event in the local Pg-Sg distance range.

**Figure 10** The same as in Figure 9 for an event in the Pn distance range. Note that in the record at 405 km Pn and Pg have already about the same amplitude, whereas at shorter distances Pn is much smaller or not even

recognizable above the noise.

**Figure 11 Location** by the circle and chord method for the event **within the network**, using only records in the local Pg-Sg distance range and the  $d$  values given in Figure 9, determined by the "rule of thumb" (1). Note the good agreement between this rough solution by hand and the PC assisted record analysis, phase picks and event location.

**Figure 12 Location** by the circle and chord method for the event **outside the network**, using records in the Pn distance range and the  $d$  values given in Figure 10. Note the much worse circle crossing. It results in larger location uncertainty (long axis of the error ellipse) in N-S

direction, which is perpendicular to the connection line between the network center and the source. This applies to both the manual and the PC solution. Again the two agree rather well.

## 6 Determination of source depth

The above exercise was run on the assumption of a (near) surface source for which effects of source depth  $h$  are negligible. However, as mentioned earlier, the overshoot of the distance circles drawn around the stations is largely due to the negligence of  $h$  and the fact that for  $h > 0$  it holds  $d$ (= hypocentral distance)  $>$   $D$ (= epicentral distance).

However, the records in Figure 9 relate to a local earthquake of larger source depth, in contrast to the records in Figure 10, which result from a more shallow strong mining explosion in Poland. Therefore, the overlap of circles in Figure 11 is larger than in Figure 12, although quite some uncertainties are introduced in the latter case due to more difficult phase identification, often worse SNR, less accurate onset time picking as well as pronounced lateral velocity differences towards the boundary of the East European Platform, which are not accounted for by the used simple one-dimensional travel-time model.

If, however, large circle overshoot hints to  $h \gg 0$  km one should re-calculate the station radii  $d_i$  by stepwise increasing  $h$  until for  $d_{imin}$  the “true” (better: the most likely) source depth  $h_{true}$  can approximately be estimated via the relationship

$$h_{true} = (R_i^2 - d_{imin}^2)^{1/2}.$$

The circles drawn around the stations with  $d_{imin}$  are expected to have zero (or negligible) overshoot, provided that the wave propagation conditions are sufficiently homogeneous and well represented by the assumed velocity model and further that the station reading errors of phase onset times are negligible. This is illustrated by the 3 plots in Figure 13 for another local earthquake.

**Figure 13** Sequence of circle & chord plots for an earthquake in the Vogtland swarm earthquake region of South-Eastern Germany. Assumed are different source depths for fixed hypocentral distances  $d_i$  of the  $i$  stations as calculated from the S-P travel-time differences. For  $h = 14$  km the circles cross almost ideally in one point at the epicenter.

Allowing for finite source depth also means that the travel-time curves for the direct P and S waves would no longer be straight lines with zero travel time at  $D = 0$  km. Rather, P and S would have bended travel-time curves with different finite travel times also at the epicenter. Accordingly, for constant S-P times and thus  $d$  the epicentral distance  $D$  decreases with growing depth until one gets at the epicenter position  $D = 0$  that  $d = h$ . This also explains why reliable depth estimates require records from stations in the near source area at  $D < h$ .

Both effects are well illustrated by the movies [\*\*3D-wave-prop\\_travel-times\\_qt\*\*](#) and [\*\*circles\\_depth\\_qt\*\*](#). You can activate these movies by right mouse click on the respective file name in bold blue. Note in the final travel-time-record plot shown in the first movie that actual phase onset times at some of the stations may differ by several tenths of a second from the theoretically calculated ones for an average 1-D crustal velocity model of the considered area.

The movies can also be downloaded via the summary listing *Download Programs & Files* (see Overview on the NMSOP-2 cover page and follow related instructions).

## 1 Aim

This exercise and tutorial aims at making you familiar with the basic concept of locating seismic events by means of teleseismic records from single 3-component stations. Often the results are comparably good or even better than for uncalibrated single seismic arrays.

The exercise uses teleseismic events only although the procedure outlined below is the same for local seismic events. In the latter case local travel-time curves as in Exercise EX 11.1 have to be used for phase identification and distance determination. Note however that azimuth determinations for local events are less reliable when short-period records are used. They are much more influenced by local heterogeneities in the crust than teleseismic long-period or broadband records. Accordingly, particle motion might deviate significantly from linear polarization (see Chapter 2, Fig. 2.6) and the azimuth of wave approach for local events sometimes deviates more than  $20^\circ$  ( $+ 180^\circ$ ) from the backazimuth AZI towards the source (see Chapter 11, Fig. 11.23).

## 2 Data

The following data are used in the exercise:

- two 3-component earthquake records: a) Kirnos BB-displacement seismograms (Figure 2) and b) long-period (WWSSN-LP) seismograms (Figure 3);
- simplified differential body-wave travel-time curve (with respect to the P-wave first arrival) for the distance range  $0^\circ < D \leq 100^\circ$  (Figure 4) according to the classical Jeffreys-Bullen (1970) travel-time curves;
- IASP91 table (Kennett, 1991) of travel-time differences pP-P and sP-P, respectively, as a function of epicentral distance D (in degree) and source depth h (in km) (see Table 1);
- global map of epicenter distribution with isolines of epicentral distance D (in  $^\circ$ ) and principal directions of backazimuth AZI from station CLL (Germany).

## 3 Procedure

### 3.1 Assessment of the earthquakes distance and depth range, identification of essential phases, estimation of epicentral distance D and depth h

- Identification of the very first as well as of later secondary arrivals from teleseismic events in broadband or long-period filtered records. At least P and S have to be identified. P is the first arrival (up to about 100°). For teleseismic events ( $D > 20^\circ$ ) P has its largest amplitude in the vertical component. S is the first arriving shear wave, up to about 83°, and has its largest amplitudes in horizontal components. For larger distances SKS becomes the first arriving shear wave (see t-D curves in Figure 4 and record examples in Figures 10c, 12d, 14e and 15b of DS 11.2 ). Misinterpreting it as S might result in significant underestimation of the epicentral distance.
- Determination of epicentral distance D by using the travel-time difference  $t(S-P)$  according to travel-time tables (e.g., IASPEI91; Kennett 1991) or by fitting best a set of differential travel-time curves as in Figure 4 with the identified phases in the record. Note that the records and the t-D-curves must have the same time scale. In the distance range  $20^\circ < D < 85^\circ$  the following *rule-of-thumb* allows to determine D with an error  $< 3^\circ$ :

$$D [^\circ] = [t(S-P)_{\text{min}} - 2] \times 10. \quad (1)$$

- Note, that the travel-time difference  $t(S-P)$  but also the time difference between P or PKP (beyond 105°) with other secondary phases is influenced by the source depth h. Unrecognized significant source depth might result in underestimating D by several degrees. Accordingly, it is important to assess first whether an event was deep or shallow (i.e., probably within the crust).
- For a first rough discrimination between deep and shallow earthquakes one should compare the amplitudes of body waves with that of (dispersed!) surface waves. If the latter are well developed and significantly larger in amplitude than the earlier body waves, then the event can be considered a crustal earthquake. If, however, the long-period surface waves have much smaller amplitudes than the earlier body waves or are not recognizable at all, then the earthquake is surely deeper than 100 km.
- The identification of depth phases (see Chapter 2, Fig. 2.43) is difficult for shallow events, because then they follow within a few seconds to the primary P or S onset. One may then use travel-time curves or tables for surface focus ( $h = 0$  km) or “normal depth” events ( $h = 33$  km) for estimating the distance. In any event, if  $D \gg h$ , the error in distance estimate is usually negligible.. They are crucial for improving hypocenter locations.
- However, in the case of relatively weak or absent surface waves one should look for depth phases! They are crucial for improving hypocenter locations (see discussion in section 11.5.4 of Chapter 11 and Figure 7 in IS 11.1). Examples for depth phases are given in DS 11.2, Figures 7b, 9a, 16b and in DS 11.3, Figures 3b-d and 5a. If depth phases such as pP and/or sP have been identified, h can be calculated rather reliably when the epicentral distance is roughly known. One may use for it either the differential travel-times pP-P or sP-P (see Table 2), or, if such tables are not at hand, roughly estimate h by another rule-of-thumb:

$$h [\text{km}] \approx 0.5 t(\text{pP-P}) [\text{s}] \times n \quad (2)$$

with  $n = 7$ , or 8, or 9 for  $h < 100$  km, 100–300 km, or...  $\times 9$   $h > 300$  km.

- Generally, when interpreting seismic records you should proceed as follows:

**Take interest!****Be curious!****Ask questions!**

to your seismic record

**1. Is the event NEAR ( $D < 20^\circ$ ) or TELESEISMIC ( $D > 20^\circ$ )?****Criteria:**

- |                          |                                    |                                     |
|--------------------------|------------------------------------|-------------------------------------|
| • <b>Frequencies</b>     | on SP records $f \geq 1$ Hz        | $f \leq 1$ Hz                       |
| • <b>Amplitudes</b>      | on LP records <b>not or weaker</b> | <b>large, also for later phases</b> |
| • <b>t(S-P)</b>          | $< 3.5$ min                        | $> 3.5$ min                         |
| • <b>Record duration</b> | $< 20$ min                         | $> 20$ min                          |
- (for magnitudes  $< 5$ ; may be longer for strong earthquakes)

**2. Is the event SHALLOW or DEEP ( $> 70$  km)?****Criteria:**

- |                        |                             |                                       |
|------------------------|-----------------------------|---------------------------------------|
| • <b>Surface waves</b> | on LP records <b>strong</b> | <b>weak or none</b>                   |
| • <b>Depth phases</b>  | usually <b>not clear</b>    | <b>well separated and often clear</b> |
| • <b>Waveforms</b>     | usually <b>more complex</b> | <b>more impulsive</b>                 |

**3. Is the event  $D < 100^\circ$  or  $D > 100^\circ$  ?****Criteria:**

- |                            |                                  |    |                                      |
|----------------------------|----------------------------------|----|--------------------------------------|
| • <b>Surface wave max.</b> | after P arrival $< 45 \pm 5$ min | or | $> 45 \pm 5$ min (Table 5 in DS 3.1) |
| • <b>Record duration</b>   | on LP records $< 1.5$ hours      | or | $> 1.5$ hours                        |
- (may be larger for very strong earthquakes)

**4. Is the first strong horizontal arrival S or SKS ?****Criteria:**

- |                               |                                     |                          |
|-------------------------------|-------------------------------------|--------------------------|
| • <b>Time difference to P</b> | $< 10 \pm 0.5$ min                  | $\approx 10 \pm 0.5$ min |
| • <b>Polarization</b>         | large horiz. A <b>in R and/or T</b> | <b>in R only</b>         |

**Warning !** If the first strong horizontal arrival follows P after  $\approx 10 \pm 0.5$  min it may be SKS.

**Check polarization** (see 11.2.4.3 in Chapter 11). R and T are the radial and transverse horizontal components, respectively. Misinterpreting SKS as S may yield D estimates up to  $20^\circ$  too short. Look also for later multiple S arrivals (SP, SS, SSS) with better D control.

**5. What are the first longitudinal and transverse onsets for  $D > 100^\circ$  ?**

Beyond  $100^\circ$  epicentral distance phase interpretation and distance determination from travel-time differences between secondary phases becomes more difficult. A long-period P may still arrive first, up to about almost  $150^\circ$ , yet with steadily decreasing amplitude and therefore recognizable only in records of strong earthquakes. But this P did not travel a direct mantle path, rather it has been diffracted around the core-mantle boundary. Therefore, it is termed Pdif (old nomenclature Pdiff; see Figs. 11.59 and 11.63 in Chapter 11). First onsets in SP records, however, are beyond  $100^\circ$  usually the later arriving PKiKP and PKPdf (Fig. 11.59), or, somewhat later PP. The latter is often the first strong longitudinal Z-component arrival in both SP, LP and BB records (see Figs. 11.60 and 11.63). The first strong arrivals on horizontal (R) components are PKS or SKS.

Misinterpretation of these first strong longitudinal and transverse wave arrivals as direct P and S, respectively, may result in epicentral distance estimates up to more than  $70^\circ$  too short! This, however, can be avoided by taking the criteria 3. above into account. Also note, that the travel-time difference between PKPdf and PKS or SKS is (almost) independent of distance. Therefore, these first arriving P and S waves do not allow distance to be estimated from their

onset-time difference. Rather look for later arriving multiple-reflected S waves such as SS, SSS, etc. They are usually well developed in this distance range on horizontal LP records, have a large slowness difference with respect to earlier arriving core phases and thus allow D to be estimated with an error of usually  $< 2^\circ$ .

### 3.2 Estimation of backazimuth AZI

- Identify the proper direction of P-wave first motion in the three components Z, N, E. Make sure by exact time correlation that you really compare the same first half cycles in all three records! This is particularly important, if in one of the horizontal components the first onset is very weak or near to zero. Then one might be misled and associate the stronger amplitude of a later half cycle with the first motion in the other components and gets a wrong backazimuth.
- Determine the **direction of particle motion AZI** in different horizontal quadrants from the amplitudes of first motions in the horizontal component records according to the formula

$$\text{AZI} = \arctan (|A_E/A_N|) \quad (3)$$

- If seismograph components have been calibrated properly and avail of identical frequency responses (which is the case for the records used in the two exercises below) then one just calculates the ratio between measured trace amplitudes. However, as demonstrated in Figure 1, the direction AZI may either show **towards the epicenter**, in case the first motion in Z is down (-, dilatational; see blue record traces), or away from the epicenter in the direction of wave propagation if the first motion in Z is up (+, compressional; see red record trace). In the latter case, the backazimuth BAZ, measured clockwise from north towards the source epicenter as seen from the station) is  $\text{BAZ} = \text{AZI} + 180^\circ$ .
- But the conversion from AZI into BAZ depends on the quadrant of particle motion and thus the polarity patterns in the three components. Table 1 guides you how to determine the quadrant of horizontal particle motion and then to calculate BAZ from measured AZI.

**Figure 1** Synthetic example of P-wave first motions in 3-component records (left) from which the azimuth AZI (clockwise from north towards the direction of wave-propagation), respectively the backazimuth BAZ (clockwise from north towards the direction of the source as seen from the station) can be calculated.

**Table 1** How to identify the quadrant of AZI measurement and to calculate BAZ from AZI.

| Z | N-S | E-W | AZI                      | BAZ              |
|---|-----|-----|--------------------------|------------------|
| – | +   | +   | 1 <sup>st</sup> quadrant | BAZ = AZI        |
| – | –   | +   | 2 <sup>nd</sup> quadrant | BAZ = 180° - AZI |
| – | –   | –   | 3 <sup>rd</sup> quadrant | BAZ = 180° + AZI |
| – | +   | –   | 4 <sup>th</sup> quadrant | BAZ = 360° - AZI |
| + | +   | +   | 1 <sup>st</sup> quadrant | BAZ = 180° + AZI |
| + | –   | +   | 2 <sup>nd</sup> quadrant | BAZ = 360° - AZI |
| + | –   | –   | 3 <sup>rd</sup> quadrant | BAZ = AZI        |
| + | +   | –   | 4 <sup>th</sup> quadrant | BAZ = 180° - AZI |

- If this 180° ambiguity has been resolved by taking into account the P-wave vertical component first motion polarity then one may also calculate BAZ from horizontal component records of either later cycles of P with larger amplitudes or even by using the amplitude ratio in E/N from other later phases that are polarized in the vertical propagation plane such as PP, SKS, SP etc.

### 3.3 Event location using the estimated epicentral distance D and backazimuth BAZ

- You may use a sufficiently large globe (diameter about 0.5 to 1 m), mark there the position of your station and then use a bendable ruler with the same scale in degree as your globe and an azimuth dial to find your event location on the globe.
- Another possibility is that you get a regional (Figure 5) or global map projection (Figure 6) which shows isolines of equal azimuth and distance from your station. Such maps can nowadays easily be calculated and plotted for any station with known co-ordinates together with the seismicity pattern.

## 4 Data used for the exercise

- 3-component broadband displacement records of an earthquake plotted in Figure 2;
- 3-component long-period WWSSN records of an earthquake plotted in Figure 3;
- Simplified differential travel-time curve according to the Jeffreys-Bullen model for the distance range up to 100°;
- Regional map for Europe and the Mediterranean with earthquake epicenters and isolines of D and BAZ with respect to station MOX, Germany;
- World map with epicenters and isolines of D and BAZ from station CLL, Germany;
- Table 2 of travel-time differences pP-P and sP-P as a function of distance D and depth h according to the IASP91 travel-time tables (Kennett, 1991).

**Figure 2** 3-component record of a Kirnos BB-displacement seismograph at station MOX, Germany. For response see Fig. 3.11 in Chapter 3. Original time-scale of the analog record was 15 mm/minute. All components were properly calibrated and had identical magnification.

**Figure 3** A long-period 3-component body-wave record section (WWSSN-LP simulation) of station CLL, Germany. **Insert:** Complete event record at compressed scale.

**Figure 4** Simplified Jeffreys-Bullen differential travel-time curve in the distance range  $0^\circ < D \leq 100^\circ$ . Original time scale was 15 mm = 1 min.

**Figure 5** Regional map for Europe and the Mediterranean with earthquake epicenters and isolines of D and AZI with respect to station MOX, Germany.

**Figure 6** World map with epicenters and isolines of D and AZI fort station CLL, Germany.

**Table 2** Travel-time differences pP-P and sP-P as a function of distance D and depth h according to the IASP91 travel-time tables (Kennett, 1991).

| 100                  | 6.9 | 15.4 | 20.5 | 37.3 | 54.1 | 70.7 | 87.2 | 103.2 | 134.3 | 163.0 | 190.3 | 215.7 |

## 5 Tasks

To run the exercise by hand you should first produce two paper copies of the records to be analyzed (Figures 2 and 3, respectively) and a transparent overlay copy of the differential travel-time curve in Figure 4 and. All copies should be made so as to have identical time scale.

### 5.1 Event record No. 1 (Figure 2)

5.1.1 Assess, whether the source was shallow ( $< 70$  km) or deep (Look for surface waves!)

- Shallow source?
- Deep source?

5.1.2 Look for possible depth phases. Are there any clear depth phases?

- Yes?
- No?
- Comments on the possible depth range of the EQ if you suspect pP and/or sP to arrive in the complex wave group after P?

5.1.3 If you do not find any clear depth phases use the differential travel-time curve in Figure 4 (which is for surface foci), and try to identify the principal phases in the vertical and horizontal component record.

- Which phases you have identified?
- Give reasons for your interpretation?

5.1.4 a) Measure the time difference  $t(S-P)$ , b) estimate the epicentral distance  $D$  by using Equation (1) and c) by matching  $t(S-P)$  with the  $t-D$  curve of Figure 4.

- a)  $t(S-P) =$
- b)  $D = \dots\dots^\circ$
- c)  $D = \dots\dots^\circ$

5.1.5 Determine a) the quadrant of P-wave first motion horizontal particle motion, b) AZI from the amplitude ratio  $|A_E/A_N|$  using Equation (1), and c) calculate BAZ taking into account the relationships between AZI, quadrant and BAZ in Table 1.

- a) Quadrant =
- b) AZI (MOX) =  $\dots\dots^\circ$
- c) BAZ(MOX) =  $\dots\dots^\circ$

5.1.6 Locate the epicenter on the map given in Figure 5 and name the source region.

- Source region?
- Discussion?

## 5.2 Event record No. 2 (Figure 3)

5.2.1 Assess, whether the event was shallow ( $< 70$  km) or deep by looking for possible surface waves in the full record, which is inserted at strongly compressed time scale.

- Shallow event?
- Deep event?

5.2.2 Look for possible depth phases. Are there any clear depth phases?

- Yes?
- No?
- Comments?

5.2.3 Measure the time difference (in min) between the P-wave first arrival and the five marked onsets of stronger secondary wave arrivals in the records. Write down the time differences  $X_i$ -P (in min) in the order of their appearance.

- $X_1$ -P = ,  $X_2$ -P = ,  $X_3$ -P = ,  $X_4$ -P = ,  $X_5$ -P = ?

5.2.4 In order to match these travel-time differences with the differential t-D curve in Fig. 4 plot them with the same time scale as your overlay on the edge of a sheet of paper. Then place the P-wave onset mark on distance scale and move it there along until you match the onset marks of the later onsets with relevant travel-time curves in Figure 4. a) Read the distance D (in  $^\circ$ ) related to this best fit with as many as possible of your onset marks and b) identify the related phases and write their names on the onsets!

a)  $D$  (CLL) = ..... $^\circ$ ,

b)  $X_1$  = ,  $X_2$  = ,  $X_3$  = ,  $X_4$  = ,  $X_5$  =

- Comments, which support your phase interpretations ?

5.2.5 Determine a) the quadrant of particle motion, b) AZI and c) BAZ as in task 4.1.5.

a) Quadrant =

b) AZI (CLL) = .....  $^\circ$

c) BAZ(CLL) = .....  $^\circ$

5.2.6 Locate the event as in task 5.1.6 by using Figure 6

- Name of source region/country?

## 6 Solutions

**Note:** Your estimates for the travel-time differences should be within about 0.2 min, for D within  $2^\circ$  and for the backazimuth AZI within about  $5^\circ$  of the solutions given below. They were derived by hand by the authors of this tutorial exercise, following the outlined procedures. The solutions given below are numbered according to the tasks in section 5.

## Event No. 1:

## 5.1.1

The earthquake is deeper than 70 km because no long-period and dispersive surface waves have been recorded.

## 5.1.2

On this record with low time resolution it is difficult to recognize for sure depth phases. However, they might arrive within the complex wave group that follows within about 40 s after the P onset. The ISC calculated a hypocenter depth  $h = 111$  km and an epicentral distance  $D = 20.24^\circ$  for station MOX. According to the IASP91 (Kennett, 1991) differential travel-time table for depth phases pP should then arrive about 21 s and sP about 35 s after P.

| pP-P     |     | Depth of source [km] |      |      |      |      |      |      |      |      |      |      |      |
|----------|-----|----------------------|------|------|------|------|------|------|------|------|------|------|------|
| $\Delta$ | 15. | 35.                  | 50.  | 100. | 111  | 150. | 200. | 250. | 300. | 400. | 500. | 600. | 700. |
|          | s   | s                    | s    | s    | s    | s    | s    | s    | s    | s    | s    | s    | s    |
| 2        | 3.6 | 7.5                  |      |      |      |      |      |      |      |      |      |      |      |
| 4        | 3.6 | 7.5                  |      |      |      |      |      |      |      |      |      |      |      |
| 6        | 3.6 | 7.5                  |      |      |      |      |      |      |      |      |      |      |      |

| 22       | 6.4 | 14.0                 | 18.2 | 32.2 | 46.0 | 59.9 | 73.8 | 87.3 | 113.0 | 135.2 | 155.5 | 171.4 |  |
| 24       | 6.6 | 14.5                 | 19.0 | 34.0 | 48.6 | 63.0 | 77.1 | 90.7 | 116.5 | 139.1 | 159.6 | 177.1 |  |

Accordingly, the first two sharp recognizable onsets after P on the Z component record are most likely the depth phases pP and sP (see Figure 7), not PP and PPP, as plotted in the simplified J-B-differential t-D curves of Figure 4. According to more recent travel-time models such as IASP91 (see DS 2.1) PP and PPP will appear only for  $D \geq 30^\circ$ .

**Figure 7** Cutout of the vertical component record in Figure 2, stretched in time-scale. This allows better recognition of the depth phase onsets pP and sP at the expected arrival times after P for an earthquake at 111 km depth (as calculated by the ISC).

### 5.1.3

You should have identified at least P on the Z component, the S wave as the largest onset on the E component, and SS (with longer period than S) on the N component.

### 5.1.4

The results are shown in Figures 8 and 9. Note that the ISC calculated for MOX, based on the global network location,  $D = 20.24^\circ$ .

**Figure 8**

**Figure 9**

### 5.1.5

- 2<sup>nd</sup> quadrant of P-wave first particle motion;
- $\text{AZI}(\text{MOX}) = \arctan(|A_E/A_N|) \approx \arctan(4/3) \approx 53^\circ$
- $\text{BAZ} \approx 125^\circ$ .

### 5.1.6

Using the results from 5.1.4 and 5.1.5 (Figure 9) together with the map in Figure 5 the earthquake was located in the coastal area of **southern Turkey**. Locating a sub-crustal earthquake there makes sense, because the African Plate is sub-ducted underneath southern Turkey. Figure 10 shows the excellent agreement of the single station 3-component broadband solution with the global network solution of the ISC. **The two epicenter positions differ by only about  $0.7^\circ$ !**

Figure 10

**Event No. 2:**

## 5.2.1

Shallow teleseismic earthquake with strong surface waves (see insert of Figure 3;  $A_{\max}$  after about 37 min).

## 5.2.2

No depth phases recognizable in the LP records (NEIC reported for this earthquake a hypocenter depth of  $h = 19$  km).

## 5.2.3

$X1-P \approx 3.65$  min,  $X2-P \approx 10.5$  min,  $X3-P \approx 11.3$  min,  $X4-P \approx 12.2$  min,  $X5-P \approx 17$  min

## 5.2.4

- $D(CLL) \approx 93^\circ \pm 1^\circ$  for the best match of the travel-time differences given under 5.2.3 with the with the travel-time curve shown in Figure 4. NEIC-PDE gives for station CLL  $92.6^\circ$ .
- The identified phases, which match best the travel-time differences to P given under 5.2.3 are:  $X1 = PP$ ,  $X2 = SKS$ ,  $X3 = S$ ,  $X4 = PS/SP$ ,  $X5 = SS$
- Both SKS and PS are strongest in the horizontal component E where also P has its largest (radial) horizontal amplitude. At about the time of the PS arrival in N there appears also in Z a clear energy arrival (SP↓). S arrives later than SKS and is strongest in the N (transverse) component only.

The summary results are plotted in Figure 11.

Figure 11

## 5.2.5

- Quadrant ? Transition from 1<sup>st</sup> to 2<sup>nd</sup> because of large eastward P-wave motion; first motion in N-S component not measurable
- AZI (CLL)  $\approx 90^\circ$
- BAZ (CLL)  $\approx 270^\circ$  because + first motion in Z and E relates to a source in the W.

**Comment:** Recognizable P-wave upward (+) motion in the N component begins only more than 6 s later than in the Z component, thus being related to the strong downward (-) P-wave motion! Therefore, the azimuth might be a few degrees further north. In fact, NEIC-PDE gives for CLL AZI =  $272.3^\circ$ .

## 5.2.6

Using the map in Figure 6 for station CLL the source is located near **Ecuador**. NEIC-PDE gives as epicenter coordinates  $0.59^\circ\text{S}$  and  $80.39^\circ\text{W}$ , i.e., near coast of Ecuador. The difference between these two locations is  $< 3^\circ$  (see Figure 12) and would be even less, if the weak N-S first motion could have been resolved by appropriate interactive amplitude scaling.

+ CLL solution  $\Rightarrow$  **Ecuador,  $D \approx 93^\circ$ , BAZ  $\approx 270^\circ$  + a few degrees N?**

★ NEIC solution: **Ecuador,  $0.59^\circ\text{S}$ ,  $80.39^\circ\text{W}$ ;  $D(\text{CLL}) = 92.6^\circ$ ,  $\text{BAZ}(\text{CLL}) = 272.3^\circ$**

Figure 12

## Acknowledgment

Figures 2 and 4 as well as Table 2 had been compiled by W. Strauch and K. Wylegalla for an earlier version of this exercise.

## 1 Aim

This manual exercise aims at making you familiar with the identification of both direct and multiple-reflected longitudinal core phases and their use in location and magnitude determination. Clear short-period vertical component PKP seismograms of a single station contain all information needed to determine *source depth*  $h$ , *epicentral distance*  $D$  and *magnitude*  $m_b$  with an accuracy of  $\pm 30$  km, better  $\pm 1.5^\circ$  and  $\pm 0.3$  magnitude units, respectively. In case of strong seismic sources and the availability of identically calibrated horizontal components with good signal-to-noise ratio, additionally the backazimuth to the source can be determined with an accuracy of about  $\pm 5^\circ$ -  $10^\circ$  and thus the approximate location. Additionally, the identification of late reflected core phases and their use in distance determination is practiced. These phases are very suitable for calculating the epicentral distance since their relative travel-time difference to the related first arrival P or PKP is nearly independent of source depth.

## 2 Data

- Figure 1: Compilation of typical analog short-period recordings at station MOX, Germany, of the different direct core phases from earthquakes between  $135^\circ < D < 160^\circ$ ;
- Figure 2: Plots of digital broadband records of the German Regional Seismograph Network (GRSN), filtered according to a WWSSN-SP response, from a Fiji-Island earthquake within the distance range  $148.4^\circ$  (CLL) to  $152.2^\circ$  (BFO);
- Figure 3: Three record examples with PKPab, bc and df phases to be analyzed;
- Figure 4: Four records with later longitudinal core phases to be evaluated;
- Figure 5: Travel times and paths of the direct longitudinal core phases and their relationship to the P-wave velocity model of the Earth;
- Figure 6: Ray path of the reflected core phases  $P'P'$  (or PKPPKP) and PKKP;
- Figure 7: Differential travel-time curves pPKP-PKP for  $D = 150^\circ$ ;
- Figure 8: Differential travel-time curves PKPbc-PKPdf (PKP1-PKIKP) and PKPab-PKPdf (PKP2-PKIKP);
- Figure 9: Differential travel-time curves PKKP-P and PKKP-PKP, respectively;
- Figure 10: Differential travel-time curves PKPPKP-P.
- Figure 11: Record with identified onsets.
- Figure 12: Magnitude calibration functions for PKPdf (old PKIKP), PKPbc (old PKP1) and PKPab (old PKP2).

Note 1: All differential travel-time curves given in this exercise have been calculated according to the earth model IASP91 (Kennett and Engdahl, 1991). The more recent model AK135 (Kennett et al., 1995) yields still better travel-times for core phases. The difference, however, is more significant for absolute and usually negligible for differential travel times.

Note 2: The first record example in Figure 1 illustrates that at  $D < 145^\circ$  small amplitude precursors PKPpre of waves scattered from the core-mantle boundary (CMB) may occur. In the case of crustal earthquakes PKPdif may additionally be followed closely by depth phases. Together this may mimic a core phase triplication typical for  $D > 146^\circ$ . Yet, in the case of deep earthquakes with sharp onsets and no or small signal coda, the triple group of phases is usually rather distinct and its typical pattern easily recognizable.

Note 3: The typical three-phase pattern PKPdif (alternative name PKIKP), PKPbc (old name PKP1) and PKPab (old name PKP2) is however well developed between  $146^\circ < D < 155^\circ$  only. Around  $145^\circ$  all three phases arrive at the same time and thus superpose to a rather strong impulsive onset.

Note 4: Beyond  $154^\circ$  still a weak intermediate phase between PKPdif and PKPab may be observed up to about  $160^\circ$  along the extrapolation of the PKPbc travel-time branch. It is, however, not PKPbc proper but rather the phase PKPdif which is diffracted around the inner-core boundary (see last record example in Figure 1).

Note 5: In the last record example of Figure 1 the well developed depth phase obviously relates to the strongest direct phase PKPab (old PKP2). The depth phases pPKP may, in the case of maximum possible source depth around 700 km, follow the related direct phases after up to about 2.5 minutes. When the primary core phases are rather strong, two or three related depth phases may be discernable.

Note 6: More examples based on plots from digital seismic records are given in DS 11.3.

Additionally, for the magnitude determinations, measured trace amplitudes have to be converted into ground motion amplitudes. For this the frequency dependent amplitude-magnification of the seismograph has to be known. It is given in Table 1.

**Table 1** Magnification MAG of ground displacement in the seismic records of earthquakes No. 1, 2 and 3 in Figure 3 when these are reproduced with a time scale of 1 mm/s.

| Period (in s) | 0.9    | 1.0    | 1.1    | 1.2    | 1.3    | 1.4    | 1.6    | 1.8    | 2.0    | 2.4    |
|---------------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| MAG Event 1   |        | 52,440 |        | 49,210 |        | 44,090 | 37,550 | 30,660 | 24,420 | 14,000 |
| MAG Event 2   |        | 26,220 |        | 24,600 |        | 22,040 | 18,770 | 15,330 | 12,210 | 7,000  |
| MAG Event 3   | 62,020 | 56,000 | 49,980 | 43,960 | 37,940 |        |        |        |        |        |

### 3 Procedure

All steps of determining  $h$ ,  $D$ ,  $AZI$  and  $mb$  will be practiced.

**Source depth** and **epicentral distance** are determined by reading the relative onset-time difference in seconds or minutes, respectively, between identified phases and using the corresponding differential travel-time curves. Note that these curves in Figures 7 and 8 have been presented with the same time-resolution as the analog records in Figure 3, i.e. with 1

mm/s. If a transparent overlay is produced from these curves, the source depth and the epicentral distance, respectively, from the records depicted in Figure 3 can be directly determined by matching the related curves with the identified onsets. Make sure that the depth and distance axes, respectively, are kept perpendicular to the center line of the record trace when matching. When reading the time differences PKKP-P and P'P'-P in Figure 4 be aware, that the time difference between subsequent traces from top to bottom is 15 minutes. Full minutes start at the left side of the 2 second long gaps or „faintings“ on the record traces.

The **backazimuth** is determined according to the instructions given under 3.2 in EX 11.2.

For epicenter **location** based on the estimated epicentral distance D and the backazimuth AZI one may use either a sufficiently large globe (diameter about 0.5 to 1 m), mark there the position of the considered station and then use a bendable ruler with the same scale in degree as your globe and an azimuth dial to find the source location on the globe. Another possibility is to use a global map projection which shows isolines of equal backazimuth and distance from your station (as Figure 5 in EX 11.2). Such maps can nowadays easily be calculated and plotted by means of computers.

The **magnitude mb(PKP)** is determined according to an experimental calibration function for magnitude determinations based on short-period readings of various PKP phases in the distance range 145° to 164°. It has been developed by S. Wendt (Bormann and Wendt, 1999). Its world-wide testing is recommended. The following relationship is used:

$$mb(PKP) = \log_{10} (A/T) + Q(\Delta, h)_{PKP} \quad (1)$$

with amplitude A in  $\mu m$  ( $10^{-6}$  m). If more than one PKP phase PKPab, PKPbc and/or PKPdc can be identified and A and T been measured then the individual phase magnitudes should be determined first and then the average magnitude be calculated. The latter provides a more stable estimate.

## 4 Tasks

- 4.1 Train yourself first by matching the travel-time curve overlay of Figure 8 with the onsets marked in Figure 1, taking into account the distance and focal depth given for each earthquake. Also consult Figure 2 and the related notes 1 to 6 in section Data above. Then mark on the records in Figure 3 for all three earthquakes the onset times of recognizable phases and give them names, both for the early and the late arrivals (depth phases).
- 4.2 Measure the time difference pPKP-PKP for the strongest PKP arrival and its respective depth phase and determine the source depth for all three earthquakes by using the differential travel-time curves given in Figure 7. Note: If the pPKP group is less distinct and its different onsets can not be well separated then relate the depth phase to the strongest direct PKP arrival.
- 4.3 Determine the epicentral distance D (in °) of the three earthquakes shown in Figure 3 by using the differential travel-time curves shown in Figure 8 taking into account for each event the source depth determined under 4.2.

- 4.4 Measure the time difference between the P-wave first arrivals and the PKKP or P'P' phases marked in the four records presented and determine the epicentral distance  $D$  for these earthquakes by using the differential travel-time curves shown in Figures 9 and 10, respectively.
- 4.5 Estimate from the three-component record in Figure 3 (event No. 3) for the strongest phase the backazimuth AZI according to relationship and instructions given under 3.2 of EX 11.2.
- 4.6 Try to find for event No. 3, which had been recorded at the station CLL in Germany, the source location on the map shown in Figure 5 of EX 11.2. Give the name of the source area.
- 4.7 Measure the trace amplitudes  $B$  (in mm) and related periods  $T$  for all identified phases of direct PKP in Figure 3 and convert them into “true ground motion” amplitudes  $A$  (in nm) by means of Table 1 given above in section Data.
- 4.8 Determine  $\log(A/T)$  and estimate the related values for  $\sigma(D, h)$  from Figure 12. Note that these values are valid for amplitudes in  $\mu\text{m}$  only! Correct them for nm.
- 4.9 Give the individual magnitude estimates for PKPab, PKPbc and PKPdf,
- 4.10 Calculate the average  $\bar{m}_b(\text{PKP})$ .
- 4.11 Compare your results with the respective solutions given by the NEIC for these three earthquakes and assess the achievable accuracy of respective individual source parameter calculations at single stations, even when based on analog recordings only and simple analysis tools.

## 5 Solutions

5.1 See Figure 11.

5.2 NEIC gave for the three earthquakes the following hypocentral depths:

- No. 1  $h = 435 \text{ km}$
- No. 2  $h = 235 \text{ km}$
- No. 3  $h = 540 \text{ km}$

Your own depth estimates should be within about  $\pm 30 \text{ km}$  of these values. But this does not mean that your value is worse than that given by NEIC. It may be even better, because NEIC mostly does not use depth phases to constrain its solutions from direct P-wave readings.

5.3 NEIC calculated for the stations which recorded the three earthquakes in Figure 3 the following epicentral distances  $\Delta = D$  (in  $^\circ$ ):

- No. 1  $D = 148.5^\circ$
- No. 2  $D = 159.5^\circ$
- No. 3  $D = 150.3^\circ$

Using the recommended travel-time curves, your estimates should be within  $\pm 1.5^\circ$  of these values.

5.4 NEIC calculated for the station CLL which had recorded the earthquakes shown in Figure 4 the following epicentral distances:

- No. 1       $D = 98.5^\circ$   
 No. 2       $D = 111.2^\circ$   
 No. 3       $D = 66.3^\circ$   
 No. 4       $D = 57.3^\circ$

Using the recommended travel-time curves, your estimates should be within  $\pm 1.5^\circ$  to NEIC.

5.5  $AZI \approx 22^\circ$ . Your own estimate should be within  $\pm 5^\circ$  of this value.

#### 5.6 Fiji Islands

|                        |                                                   |
|------------------------|---------------------------------------------------|
| 5.7 Event No. 1: PKPdf | B = 0.5 mm, T = 1.5 s $\rightarrow$ A = 12.2 nm   |
| PKPbc                  | B = 3.9 mm, T = 1.0 s $\rightarrow$ A = 74.4 nm   |
| PKPab                  | B = 3.0 mm, T = 1.0 s $\rightarrow$ A = 57.2 nm   |
| Event No. 2: PKPdf     | B = 2.9 mm, T = 2.4 s $\rightarrow$ A = 414.3 nm  |
| PKPab                  | B = 8.2 mm, T = 2.0 s $\rightarrow$ A = 671.6 nm  |
| Event No. 3: PKPdf     | B = 0.95 mm, T = 1.3 s $\rightarrow$ A = 21.6 nm  |
| PKPbc                  | B = 20.4 mm, T = 1.0 s $\rightarrow$ A = 329.0 nm |
| PKPab                  | B = 6.5 mm, T = 1.0 s $\rightarrow$ A = 116.1 nm  |

|                        |                    |                                    |
|------------------------|--------------------|------------------------------------|
| 5.8 Event No. 1: PKPdf | $\log(A/T) = 0.9$  | $\sigma_{PKPdf}(\Delta, h) = 3.95$ |
| PKPbc                  | $\log(A/T) = 1.89$ | $\sigma_{PKPbc}(\Delta, h) = 3.15$ |
| PKPab                  | $\log(A/T) = 1.76$ | $\sigma_{PKPab}(\Delta, h) = 3.39$ |
| Event No. 2: PKPdf     | $\log(A/T) = 2.24$ | $\sigma_{PKPdf}(\Delta, h) = 3.8$  |
| PKPab                  | $\log(A/T) = 2.53$ | $\sigma_{PKPab}(\Delta, h) = 3.55$ |
| Event No. 3: PKPdf     | $\log(A/T) = 1.22$ | $\sigma_{PKPdf}(\Delta, h) = 3.94$ |
| PKPbc                  | $\log(A/T) = 2.52$ | $\sigma_{PKPbc}(\Delta, h) = 3.23$ |
| PKPab                  | $\log(A/T) = 2.06$ | $\sigma_{PKPab}(\Delta, h) = 3.55$ |

5.9 Event No. 1:  $mb(PKPdf) = 4.85$ ;  $mb(PKPbc) = 5.04$ ;  $mb(PKPab) = 5.15 \rightarrow \bar{mb}(PKP) = 5.0$   
 Event No. 2:  $mb(PKPdf) = 6.0$ ;  $mb(PKPab) = 6.1 \rightarrow \bar{mb}(PKP) = 6.0$   
 Event No. 3:  $mb(PKPdf) = 5.19$ ;  $mb(PKPbc) = 5.75$ ;  $mb(PKPab) = 5.61 \rightarrow \bar{mb}(PKP) = 5.5$

5.10 NEIC gave for these three events, based on teleseismic P-wave readings only:

- Event No. 1:  $mb = 5.0$ ,  
 Event No. 2:  $mb = 5.5$ ,  
 Event No. 3:  $mb = 5.3$

5.11 Using the calibration curves for PKP waves one can get quick  $mb$  estimates from readings of PKP amplitudes at individual stations with simple analysis tools which are within about  $\pm 0.5$  magnitudes units to the  $mb$  estimates of global seismological services. Your distance estimates should also be within  $\pm 1.5^\circ$  even when using only low-resolution analog data and visual time picks. The general source area can be determined properly, even for very

distant events, on the basis of properly mutually calibrated 3-component recordings of single seismic stations.

$D = 135.5^\circ$   
 $h = 60 \text{ km}$   
 $mb = 5.9$   
 Santa Cruz Islands

$D = 146.7^\circ$   
 $h = 543 \text{ km}$   
 $mb = 5.9$

 South of Fiji Islands

$D = 159.5^\circ$ ,  $h = 231 \text{ km}$   
 $mb = 5.5$ , Kermadec Islands

**Figure 1** Examples of short-period analog records of stations CLL and MOX of longitudinal core phases in the distance range  $135^\circ < D < 160^\circ$ . Time scale: 1 mm/s on all records.

**Figure 2 Top:** Short-period filtered seismograms (WWSSN\_SP simulation) recorded at 9 GRSN stations from a deep earthquake in the Fiji Islands (Sept. 30, 1994,  $m_b = 5.1$ ,  $h = 643$  km). All traces are time-shifted and aligned with respect to PKPdf and sorted according to epicentral distance  $D$  which is  $148.4^\circ$  for CLL and  $152.2^\circ$  for the most distant station BFO.

**Bottom:** The same trace of station CLL as above but with enlarged amplitude and time resolution.

**Figure 3** Short-period records of direct longitudinal core phases from three earthquakes. Time scale: 1 mm/s if plotted 1:1.

24.08.1995 Mariana Islands: H = 01:55:34.4, D(PLL) = ° ?, h = 588 km,  $m_b = 6.0$

13.07.1994 Banda Sea: H = 11:45:23.4, D(PLL) = ° ?, h = 159 km,  $m_b = 6.5$

08.08.1994 Myanmar: H = 21:08:31.7, D(PLL) = ° ?, h = 122 km,  $m_b = 6.1$

18.02.1996 North of Ascension Island: H = 23:49:27.8, D(PLL) = ° ?, h = 10 km,  $m_b = 6.3$

**Figure 4** Records of station CLL of later reflected longitudinal core phases (PKKP and P'P').

**Figure 5** Ray paths and travel-time curves of direct longitudinal core phases for  $D > 140^\circ$  according to the velocity model IASP91 (Kennett, 1991).

**Figure 6** Ray paths of the reflected core phases P'P' (or PKPPKP) and PKKP, respectively.

**Figure 7** Travel-time differences between the PKP arrivals for the branches ab, bc and df, respectively, and their related depth phases at an epicentral distance of  $D = 150^\circ$ .

**Figure 8** Travel-time differences between the PKPdf first arrival and the later arrivals PKPbc and PKPab, respectively, for different source depths. The dotted continuation of the branch

PKPbc-PKPdif relates to the approximate differential arrival time of the weak phase PKPdif (PKP diffracted around the inner-core boundary).

### PKKP - P and PKKP - PKP

**Figure 9** Comprison between theoretical (IASP 91) and observed travel-time differences for PKKP-P and PKKP-PKP at station CLL as a function of epicentral distance and source depth.

**Figure 10** Comparison between theoretical (IASP91) and observed travel-time differences PKPPKP - P at station CLL depending on epicentral distance.

**Figure 11** Reproduction of the records of event No. 3 with onsets (dots) marked and names of identified phases given on the vertical component. Only the onset of the depth phase PKPbc can be picked without any doubt. However, when taking the time differences between the three direct phases from the beginning of the record into account one recognizes prior and after pPKPbc changes in the waveforms just at the same time differences as for the primary phases. In the records of earthquakes No. 1 and No. 2 in Figure 3 only the depth phases pPKPbc and pPKPab can be picked at about 119 s and 60 s after PKPbc and PKPab, respectively.

**Figure 12** Calibration functions according to S. Wendt for the determination of mb(PKP) for PKIKP = PKPdf, PKP1 = PKPbc and PKP2 = PKPab (see Bormann and Wendt, 1999).

## 1 Introduction

The exact location of any source, radiating seismic energy, is one of most important tasks in practical seismology and from time to time most seismologists have been involved in this task. The intention here is to describe the most common location methods without going into the mathematical details, which have been described in numerous textbooks and scientific papers but to give some practical advice on seismic source location. Chapter 9 gives more information about the usage of seismic arrays for seismic source location.

In the case of an earthquake, the source location is defined by its hypocenter ( $x_0, y_0, z_0$ ) and the origin time  $t_0$ . The hypocenter is commonly considered to be the physical location of the starting (or initiation) point of the rupture process, usually given in longitude ( $x_0$ ), latitude ( $y_0$ ), and depth below the surface ( $z_0$  [km]). For simplicity, the hypocenter will be labeled  $x_0, y_0, z_0$  with the understanding that it can be either measured in geographical or Cartesian coordinates, i.e., in [deg] or [km], respectively. The origin time is the start time of the earthquake rupture. The epicenter is the projection of the hypocenter on the Earth's surface ( $x_0, y_0$ ). When the earthquake is large, the physical dimension of the rupture zone can be several hundred square kilometers and the hypocenter can in principle be located anywhere on the rupture surface with consequences also for the position of the related epicenter on the Earth's surface.

The hypocenter and origin time are determined by arrival times, incidence direction (backazimuth) and/or horizontal velocity of seismic phases radiated by the first break of the earthquake rupture. This is true when using any P or S phases since their propagation velocity is always larger than the rupture velocity. Therefore, P- or S-wave energy emitted from the end of a long rupture will always arrive later than energy radiated from its beginning. Standard earthquake catalogs (such as from the International Seismological Center, ISC or the National Earthquake Information Center (NEIC) of the USGS) report origin times OT and locations based primarily on arrival times of high-frequency first P-type arrivals. These OT/location parameters can be quite different from the centroid time and centroid location obtained by moment-tensor inversion of long-period waves, which may be, for really great earthquakes, even more than a minute later than OT and more than hundred kilometers off the initial hypocenter. The reason is that these centroid solutions represent the average time and location for the entire seismic moment released by the earthquake, assuming that the latter can be considered as a point source in space with a prescribed symmetric triangular moment-rate function. Yet, even this assumption does not always hold, especially for great multiple-rupture events (e.g., Chapter 3, Fig. 3.7; Kikuchi and Fukao, 1987; Tsai et al., 2005).

## 2 Single station location

In general, epicenters are determined using many seismic phase observations from different seismic stations. However, it is also possible to locate a seismic source using a single 3-component station. Since the vector of P-wave motion is polarized in the vertical plane of propagation (see Chapter 2) it can be decomposed into a vertical and a radial component of motion. This allows calculating the backazimuth **BAZ** to the epicenter (see Figure 1). The backazimuth is defined as the direction angle from the station towards the epicenter, measured clockwise from North. The radial component of P can be reconstructed from the records of the 2 horizontal seismometer components **N**(orth)-**S**(outh) and **E**(ast)-**W**(est) and the azimuth **AZI** of particle motion can be calculated via the amplitude ratio  $A_E/A_N$  of the first P-phase arrival:

$$AZI = \arctan A_E/A_N. \quad (1)$$

However, eq. (1) leaves an ambiguity of  $180^\circ$  since the first motion (FM) polarity in the vertical component can be up or down. To get the correct **BAZ** this has to be accounted for. Only if the first motion on the vertical component of the P phase is downward, the related horizontal particle motion shows towards the epicenter and then, when **AZI** is measured in the first quadrant, holds **BAZ** = **AZI**. The opposite is the case when the first motion in Z is

upward, due to an outward directed motion at the source which corresponds by definition to a compressional first motion arriving at the station. In this case the radial component of the P phase motion is directed away from the hypocenter and thus  $\text{BAZ} = \text{AZI} + 180^\circ$  (see Figure 1). For details see Table 1 in exercise EX 11.2.

**Figure 1** Example of P-wave first motions on 3-component records (left) from which the AZI (and thereby the BAZ) and the incidence angle  $i$  can be derived according to Eqs. (1) and (2).

The amplitude  $A_Z$  of the Z component can, together with the amplitude  $A_R = (A_E^2 + A_N^2)^{1/2}$  on the radial component, also be used to calculate the *apparent angle of incidence*  $i_{\text{app}} = \arctan(A_R / A_Z)$  of a P wave. However, according already to Wiechert (1907) the true incidence angle  $i_{\text{true}}$  of a P wave is a function of the mean  $v_P$ -to- $v_S$  ratio in the crust below the station

$$i_{\text{true}} = \arcsin \left[ \frac{v_P}{v_S} \times \sin(0.5 \times i_{\text{app}}) \right], \quad (2)$$

with the difference accounting for the amplitude distortion due to the reflection of P and SV-converted wave energy at the free surface. Knowing the incidence angle  $i_0$  and the local seismic velocity  $v_0$  below the observing station, we can calculate the apparent horizontal propagation velocity  $v_{\text{app}}$  of this seismic phase with

$$v_{\text{app}} = v_0 / \sin i_0. \quad (3)$$

One should note, however, that the here described measured  $i_{\text{app}}$  and thus  $v_{\text{app}}$  values at a given station depend on the dominant frequency of the seismic record (see Chapter 2, Fig. 2.6). Therefore, these values are representative for the uppermost layers of the Earth corresponding to the dominant wavelength of the observed phase and not for the incidence angle and apparent horizontal velocity directly underneath the Earth's surface.

In the case of slowly emerging first P swings (e.g., Figure 6 and 8 in IS 11.4) or when analyzing narrow-band high frequency data (e.g., Chapter 4, Figs. 4.9 and 4.10, and Chapter 16, Fig. 16.25) it might not be possible to read correctly the amplitude and polarity of the first break (see Chapter 4, Figs. 4.9 and 4.10). However, the amplitude ratio between the components should remain constant, not only for the first swing of the P phase but also for the following oscillations of the same phase, provided that they are not yet distorted by superposition with laterally refracted (scattered) wave energy, as often the case in high-frequency records. If this condition is fulfilled, we can, with digital data, use the predicted coherence method (Roberts et al., 1989) to automatically calculate backazimuth as well as the angle of incidence. This is much more reliable and faster than using manually read first motion amplitudes for calculating the backazimuth from 3-component records of single stations and has become a routine practice (e.g., Saari, 1991).

In the case of seismic arrays, apparent velocity and backazimuth can directly be measured by observing the propagation of the seismic wavefront with array methods, independently from the local seismic velocities below the station (see Chapter 9). As we show later, backazimuth observations are useful in better constraining epicenter locations and in associating observations to a seismic event. Knowing the incidence angle  $i_o$  at the station and implicitly the ray parameter  $p = \sin i_o / v_o$  of an onset at the station helps to identify the seismic phase and to calculate the epicentral distance via the, from Earth models theoretically known, distance-dependent slowness (or ray parameter) of different seismic phases.

With a single station we have now the direction to the seismic source. The distance can also be obtained from the difference in arrival time of two phases, usually P and S. If we assume a constant velocity, and origin time  $t_0$ , the P- and S-arrival times can then be written as

$$t_p = t_0 + D/v_p \quad t_s = t_0 + D/v_s \quad (4)$$

where  $t_p$  and  $t_s$  are the P- and S-arrival times respectively,  $v_p$  and  $v_s$  are the P and S velocities respectively and  $D$  is the epicentral distance for surface sources; or the hypocentral distance  $d$  for deeper sources. By eliminating  $t_0$  from Equation (4), the distance can be calculated as

$$D = (t_s - t_p) \frac{v_p \cdot v_s}{v_p - v_s} \quad (5)$$

with  $D$  in km and  $t_s - t_p$  in seconds. But Equation (5) is applicable only for the travel-time difference between  $S_g$  and  $P_g$ , i.e., the direct crustal phases of S and P, respectively, provided that the ratio  $v_p/v_s$  does not change within the crust.  $P_g$  and  $S_g$  are first onsets of the P- and S-wave groups of local events only for distances up to about 100 – 250 km, depending on crustal thickness and source depth within the crust. Beyond these distances the phases  $P_n$  and  $S_n$ , being either head waves critically refracted at the Mohorovičić discontinuity or waves diving as body waves in the uppermost part of the upper mantle, become the first onsets (see Fig. 2.32 in Chapter 2 and Fig. 11.40 in Chapter 11). The “cross-over” distance  $x_{co}$  between  $P_n$  and  $P_g$  (or  $P_b$ ) can be approximately calculated for a (near) surface focus from the relationship

$$x_{co} = 2 z_m \{ (v_m - \bar{v}_p) (v_m + \bar{v}_p) \}^{-1/2}, \quad (6)$$

with  $\bar{v}_p$  – average crustal P velocity,  $v_m$  – sub-Moho P velocity, and  $z_m$  – crustal thickness. Inserting the rough average values of  $\bar{v}_p = 6$  km/s and  $v_m = 8$  km/s we get, as a “rule of thumb”,  $x_{co} \approx 5 z_m$ . At smaller distances we can be rather sure that the observed first arrival is Pg. Note, however, that this “rule of thumb” is valid for surface focus only. As demonstrated with Fig. 2.40 in Chapter 2, the crossover distance is only about half as large for near Moho earthquakes and also the dip of the Moho and the direction of observation (up- or downdip) does play a role.

Examples for calculating the epicentral distance  $D$  and the origin time  $OT$  of near seismic events by means of a set of local travel-time curves for Pn, Pg, Sn and Sg (or Lg) are given in exercise EX 11.1. The lower crustal phases Pb and Sb are here less important since they may form only over a very short epicentral distance range the first arrivals of the P and S onsets. In the absence of local travel-time curves for the area under consideration one can use Equation (5) for deriving a “**rule of thumb**” for approximate distance determinations from travel-time differences Sg-Pg. For an ideal Poisson solid  $v_s = v_p/\sqrt{3}$ . This is a good approximation for the average conditions in the crust. With this follows from Equation (5):  $D = (t_{Sg} - t_{Pg}) \times 8.0$  for “normal, medium age” crustal conditions with average  $\bar{v}_p = 5.9$  km/s, or  $D = (t_{Sg} - t_{Pg}) \times 9.0$  for old Precambrian continental shields with rather large average  $\bar{v}_p = 6.6$  km/s. However, if known, the locally correct  $v_p/v_s$  ratio should be used to improve this “**rule of thumb**”. If the distance is calculated from the travel-time difference between Sn and Pn, another good rule of thumb is  $D = (t_{Sn} - t_{Pn}) \times 10$ . It may be applicable up to about 1000 km epicentral distance.

For epicentral distances between about  $20^\circ < \Delta < 100^\circ$  the relationship  $\Delta^\circ = \{(t_s - t_p)_{\min} - 2\} \times 10$  still yields reasonably good epicentral distance estimates with errors  $< 3^\circ$ , however, beyond  $D = 10^\circ$  the use of readily available global travel-time tables such as IASP91 (Kennett and Engdahl, 1991; Kennett, 1991), SP6 (Morelli and Dziewonski, 1993), or AK135 (Kennett et al., 1995; now standard at the NEIC and the ISC) is strongly recommended for more accurate theoretical travel-time and epicentral distance calculations.

With both backazimuth and epicentral distance, the epicenter of a seismic event can be obtained by measuring off the distance along the backazimuth of approach. Finally, knowing the epicentral distance, we can calculate the P-wave travel time and thereby get the origin time using the P-arrival time (see EX 11.2 for location of teleseismic events by means of 3-component records).

It is important to mention at this point that the described single station location procedures cannot resolve the depth of a seismic event, unless the station analyst is able to surely identify depth phases in the record and determine the source depth from their time difference to the related primary phases. Otherwise, single station location is a pure epicenter and not hypocenter determination method.

### 3 Multiple station location

#### 3.1 Manual location

When at least 3 stations are available, a simple manual location can be made from drawing circles (the circle method) with the center at the station locations and the radii equal to the hypocentral distances calculated from the S-P times (see Figure 2).

**Figure 2** Location by the “circle and chord” method. The stations are located in S1, S2 and S3. The epicenter is found within the shaded area where the circles overlap. The best estimate is the crossing of the chords, which connect the crossing points of circle pairs.

These circles will rarely cross in one point. This may be due to errors in the onset-time readings, in the assumed travel-time or related velocity model and/or that we have wrongly assumed a surface focus. In fact,  $t_s - t_p$  is the travel-time difference for the hypocentral distance  $d$ , which is for seismic sources with  $z > 0$  km generally larger than the epicentral distance  $\Delta$  (or  $D$ ). Therefore, the circles drawn around the stations with radius  $d$  will normally not be crossing at a single point at the epicenter but rather “overshooting”. The amount of overshoot depends on source depth but also on not accounted lower than average velocity inhomogeneities. One should therefore fix the epicenter either in the “center of gravity” of the overlapping area (shaded area in Figure 2) or draw “chords”, i.e., straight lines passing through the crossing points between two neighboring circles. These chord lines intersect in the epicenter (see Figure 1 in EX 11.1). In Section 7 of this exercise and in the animation linked with it, it is illustrated how the source depth can then be determined by iteratively minimizing the overshoot. Still other methods exist (e.g., Båth, 1979) to deal with this depth problem (e.g., the hyperbola method which uses P-wave first arrivals only and assumes a constant P-wave velocity). A detailed description of the method can be found in Pujol (2004).

During the last years Earthquake Early Warning Systems (EEWS) became more in focus and for such monitoring systems quick and reliable earthquake location methods are needed. Therefore, all graphical location algorithms became again more interesting. One approach to solve the problem is using the order of first arrival times to locate the event (Nicholson et al., 2004; Rosenberger, 2009) or applying derivatives of the hyperbola method (e.g., Font et al., 2004; Horiuchi et al., 2005; Satriano et al., 2008).

### 3.2 The Wadati diagram

With data from several stations available from a local or regional seismic source, the origin time can be determined by a very simple technique called Wadati diagram (Wadati, 1933). Using Equation (5) and eliminating  $\Delta$ , the S-P travel-time difference can be calculated as

$$t_s - t_p = (v_p/v_s - 1) \times (t_p - t_0) \quad (7)$$

The observed S-P times are plotted against the absolute P time. Since  $t_s - t_p$  goes to zero at the hypocenter, a straight line fit on the Wadati diagram (Figure 3) gives the origin time at the intercept with the P-arrival axis and from the slope  $(v_p/v_s - 1)$  of the curve, we get the ratio  $v_p/v_s$ . Note that it is thus possible to get a determination of both the origin time and a mean  $v_p/v_s$  ratio without any prior knowledge of the crustal structure, the only assumption is that  $v_p/v_s$  is constant and that the P and S phases are of the same type like Pg and Sg, Pb and Sb or Pn and Sn. Such an independent determination of these parameters can be very useful when using other location methods.

**Figure 3** An arbitrary example of a Wadati diagram. The intercept of the best fitting line through the data with the x-axis gives the origin time OT. In the given case, the slope of the line is 0.72 so the  $v_p/v_s$  ratio is 1.72. The misfit of the data with this straight line indicates deviations from a constant  $v_p/v_s$  ratio and/or data reading errors.

The Wadati diagram is also very useful in making independent checks of the observed arrival times. Any points not fitting reasonably well with the linear relationship might be badly identified, either by not being of the same phase type or by misreading.

### 3.3 Computer location

Manual location methods provide insight into location problems; however, in practice we use computer methods. In the following, the most common ways of calculating hypocenter and origin time by computer will be discussed.

The calculated arrival time  $t_i^c$  at station  $i$  can be written as

$$t_i^c = T(x_i, y_i, z_i, x_0, y_0, z_0) + t_0 \quad (8)$$

where  $T$  is the travel time as a function of the location of the station  $(x_i, y_i, z_i)$  and the hypocenter. This equation has 4 unknowns, so in principle 4 arrival-time observations from at least 3 stations are needed in order to determine the hypocenter and origin time. If we have  $n$  observations, there will be  $n$  equations of the above type and the system is over determined and has to be solved in such a way that the misfit or residual  $r_i$  at each station is minimized.  $r_i$  is defined as the difference between the observed and calculated travel times which is the same as the difference between the observed and calculated arrival times

$$r_i = t_i^o - t_i^c \quad (9)$$

where  $t_i^o$  is the observed arrival time. In principle, the problem seems quite simple. However, since the travel-time function  $T$  is a nonlinear function of the model parameters, it is not possible to solve Equation (8) with any analytical methods. So even though  $T$  can be quite simply calculated, particularly when using a 1-D Earth model or pre-calculated travel-time tables, the non-linearity of  $T$  greatly complicates the task of inverting for the best hypocentral parameters. The non-linearity is evident even in a simple 2-D epicenter determination where the travel time  $t_i$  from the point  $(x, y)$  to a station  $(x_i, y_i)$  can be calculated as

$$t_i = \frac{\sqrt{(x - x_i)^2 + (y - y_i)^2}}{v}, \quad (10)$$

where  $v$  is the velocity. It is obvious that  $t_i$  does not scale linearly with either  $x$  or  $y$  so it is not possible to use any set of linear equations to solve the problem and standard linear methods cannot be used. This means that given a set of arrival times, there is no simple way of finding the best solution. In the following, some of the methods of solving this problem will be discussed.

### 3.3.1 Grid search

Since it is so simple to calculate the travel times of all seismic phases to any point in the model, given enough computer power, a very simple method is to perform a grid search over all possible locations and origin times and compute the arrival time at each station (e.g., Sambridge and Kennett, 1986 and 2001; Lomax, 2005). The hypocentral location and origin time would then be the point with the best agreement between the observed and calculated times. This means that some measure of best agreement is needed, particularly if many observations are used. The most common approach is to use the least squares solution, which is to find the minimum of the sum of the squared residuals  $e$  from the  $n$  observations:

$$e = \sum_{i=1}^n (r_i)^2 \quad (11)$$

The root mean squared residual RMS, is defined as  $\sqrt{e/n}$ . RMS is given in almost all location programs and commonly used as a guide to location precision. If the residuals are of similar size, the RMS gives the approximate average residual. As will be seen later, RMS only gives an indication of the fit of the data, and a low RMS does not automatically mean an accurate hypocenter determination. Generally, the precision of the computational solution, which is

based on various model assumptions, should not be mistaken as real accuracy of the location and origin time. This point will be discussed later under Section 7.

The average squared residual  $e/n$  is called the variance of the data. Formally,  $n$  should here be the number of degrees of freedom  $ndf$ , which is the number of observations minus the number of parameters in fit (here 4). Since  $n$  usually is large, it can be considered equal to the number of degrees of freedom. This also means that  $\mathbf{RMS}^2$  is approximately the same as the variance. The least squares approach is the most common measure of misfit since it leads to simple forms of the equations in the minimization problems (see later). It also works quite well if the residuals are caused by uncorrelated Gaussian noise. However in real problems this is often not the case. A particularly nasty problem is the existence of outliers, i.e., individual large residuals. A residual of 4 will contribute 16 times more to the misfit  $e$ , than a residual of 1. Using the sum of the absolute residuals as a norm for the misfit can partly solve this problem:

$$e1 = \sum_{i=1}^n |r_i|. \quad (12)$$

This is called the L1 norm and is considered more robust when there are large outliers in the data. It is not much used in standard location programs since the absolute sign creates complications in the equations. This is of course not the case for grid search. Therefore, most location programs will have some scheme for weighting out or truncating large residuals (see later), which can partly solve the problem.

Once the misfits (e.g., RMS) have been calculated at all grid points, one could assign the point with the lowest RMS as the ‘solution’. For well-behaved data, this would obviously be the case, but with real data, there might be several points, even far apart, with similar RMS and the next step is therefore to estimate the probable uncertainties of the solution. The simplest way to get an indication of the uncertainty, is to contour the RMS as a function of  $x$  and  $y$  (2-D case) in the vicinity of the point with the lowest RMS (see Figure 4).

**Figure 4** Left: RMS contours (in seconds) from a grid search location of an earthquake off western Norway (left). The grid size is 2 km. The circle in the middle indicates the point with the lowest RMS (1.4 s). Right: The location of the earthquake and the stations used. Note the elongated geometry of the station distribution. Its effect on the error distribution will be

discussed in Section 4.1 below. The RMS ellipse from the figure on the left is shown as a small ellipse in the figure at right. Latitudes are degrees North and longitudes degrees East.

Clearly, if RMS is growing rapidly when moving away from the minimum, a better solution has been obtained than if RMS grows slowly. If RMS is contoured in the whole search area, other minima of similar size might be found indicating not only large errors but also a serious ambiguity in the solution. Also note in Figure 4 that networks with irregular aperture have reduced distance control in the direction of their smallest aperture but good azimuth control in the direction of their largest aperture.

An important point in all grid-search routines is the method of how to search through the possible model space. In particular for events observed at teleseismic distances the model space can be very large. Sambridge and Kennett (2001) published a fast neighborhood algorithm to use for global grid search.

### 3.3.2 Location by iterative methods

Despite increasing computer power, seismic source locations are done mainly by other methods than grid search. These methods are based on linearizing the inversion problem. The first step is to make a guess of hypocenter and origin time ( $x_0, y_0, z_0, t_0$ ). In its simplest form, e.g., in the case of events near or within a station network, this can be done by using a location near the station with the earliest arrival time and using that arrival time as  $t_0$ . Other methods also exist (see below). In order to linearize the problem, it is now assumed that the true hypocenter is close enough to the guessed value so that travel-time residuals at the trial hypocenter are a linear function of the correction we have to make in hypocentral distance.

The calculated arrival times at station  $i$ ,  $t_i^c$  from the trial location are, as given in Equation (8),  $t_i^c = T(x_0, y_0, z_0, x_i, y_i, z_i) + t_0$  and the travel-time residuals  $r_i$  are  $r_i = t_i^o - t_i^c$ . We now assume that these residuals are due to the error in the trial solution and the corrections needed to make them zero are  $\Delta x$ ,  $\Delta y$ ,  $\Delta z$ , and  $\Delta t$ . If the corrections are small, we can calculate the corresponding corrections in travel times by approximating the travel-time function by a Taylor series and using only the first term. The residual can now be written:

$$r_i = (\partial T / \partial x_i) * \Delta x + (\partial T / \partial y_i) * \Delta y + (\partial T / \partial z_i) * \Delta z + \Delta t \quad (13)$$

In matrix form we can write this as

$$\mathbf{r} = \mathbf{G} * \mathbf{X}, \quad (14)$$

where  $\mathbf{r}$  is the residual vector,  $\mathbf{G}$  the matrix of partial derivatives (with 1.0 in the last column corresponding to the source time correction term) and  $\mathbf{X}$  is the unknown correction vector in location and origin time.

This is a set of linear equations with 4 unknowns (corrections to hypocenter and origin time), and there is one equation for each observed phase time. Normally there would be many more equations than unknowns (e.g., 4 stations with 3 phases each would give 12 equations). The best solution to Equation (13) or Equation (14) is usually obtained with standard least squares techniques. The original trial solution is then corrected with the results of Equation (13) or

Equation (14) and this new solution can then be used as trial solution for a next iteration. This iteration process can be continued until a predefined breakpoint is reached. Breakpoint conditions can be either a minimum residuum  $r$ , or a last iteration giving smaller hypocentral parameter changes than a predefined limit, or just the total number of iterations. This inversion method was first invented and applied by Geiger (1910) and is known as the ‘Geiger method’. The iterative process usually converges rapidly unless the data are badly configured or the initial guess is very far away from the mathematically best solution (see later). However, it also happens that the solution converges to a local minimum and this would be hard to detect in the output unless the residuals are very large. A test with a grid search program may tell if the minimum is local, or tests could be made with several initial locations or different velocity models.

So far we have only dealt with observations in terms of arrival times. Many 3-component stations and arrays now routinely report the backazimuth  $\phi$  of an arrival. It is then possible to locate events with only one station and P and S times (see Figure 1). However, the depth must be fixed. If one or several backazimuth observations are available, they can be used together with the arrival time observations in the inversion algorithm. The additional equations for the backazimuth residuals are

$$r_i^\phi = (\partial\phi/\partial x_i) * \Delta x + (\partial\phi/\partial y_i) * \Delta y \quad (15)$$

Equations of this type are then added to the Equations (13) or (14). The  $\Delta x$  and  $\Delta y$  in Equation (15) are the same as for Equation (13), however the residuals are now in degrees. At this point it is worth to mention that backazimuth observations constrain the epicenter of an event but are independent of source depth and source time.

In order to make an overall RMS, the degrees must be ‘converted to seconds’ in terms of scaling. For example, in the location program HYPOCENTER (Lienert et al., 1988; Lienert, 1991; Lienert and Havskov, 1995), a 10 deg backazimuth residual was optionally made equivalent to 1 s travel time residual. Using e.g., 20 deg as equivalent to 1 s would lower the weight of the backazimuth observations. Schweitzer (2001) used in the location program HYPOSAT a different approach. In this program the measured (or assumed) observation errors of the input parameters are used to individually weight all different lines of the equation system (13) or (14) before inverting it. Thereby, more uncertain observations will contribute much less to the solution than well-constrained ones and all equations become non-dimensional.

Arrays (see Chapter 9) or single stations (see Equation (3)) cannot only measure the backazimuth of a seismic phase but also its ray parameter (or apparent velocity), which is a function of epicentral distance and source depth. Consequently, the equation systems (13) or (14) to be solved for locating an event, can also be extended by utilizing such observed ray parameters  $p$  (or apparent velocities) as defining data. In this case we can write

$$r_i^p = (\partial p/\partial x_i) * \Delta x + (\partial p/\partial y_i) * \Delta y + (\partial p/\partial z_i) * \Delta z \quad (16)$$

Also equation (16) is independent of the source time but depends on the source depth. The partial derivatives are often very small but in some cases, in particular if an event is observed with only one seismic array, observed ray parameters give additional constraint for the event location.

Equations (13), (14) and (16) are written without discussing whether the applied velocity model is defined for a layered, flat or a spherical Earth model because they are exactly the same. Using a flat-Earth transformation (e.g., Müller, 1977) any radially symmetric Earth model can be transformed into a flat model. Travel times and partial derivatives are often calculated by interpolating in tables and in principle it is possible to use any Earth model including 2-D and 3-D models to calculate theoretical travel times. In practice, 1-D models are mostly used, since 2-D and 3-D models are normally not well enough known and the travel-time computations are much more time consuming. For local seismology, it is a common practice to specify a 1-D crustal model and calculate arrival times for each ray while for global models, an interpolation in travel-time tables such as IASP91 is the most common. As Kennett and Engdahl (1991) pointed out, the preferred and much more precise method for obtaining travel times from the IASP91 model or any other 1-D global Earth model (see DS 2.1) is to apply the tau-p algorithm developed by Buland and Chapman (1983). To calculate your own travel-time tables for local or global 1-D Earth models, the computer program LAUFZE can be downloaded for free either directly from the program list in the NMSOP-2 cover page folder *Download Programs and Files* or from NORSAR's anonymous ftp-server <ftp://ftp.norsar.no/pub/outgoing/johannes/lauf/>, a description of the program is annexed in PD 11.2. It allows calculating travel times for many different seismic phases and an arbitrary horizontally layered model with any combination of layers with constant velocities, gradients, or first-order discontinuities.

### 3.3.3 Example of location in a homogeneous model

The simplest location case is a source in a homogeneous medium. The arrival times can be calculated as

$$T_i = \frac{\sqrt{(x - x_i)^2 + (y - y_i)^2 + (z - z_i)^2}}{v} + t_0, \quad (17)$$

where  $v$  is the velocity. The partial derivatives can be estimated from Equation (17) and e.g., for  $x$ , the derivative is

$$\frac{\partial T_i}{\partial x} = \frac{(x - x_i)}{v} * \frac{1}{\sqrt{(x - x_i)^2 + (y - y_i)^2 + z^2}}. \quad (18)$$

Similar expressions can be derived for  $y$  and  $z$ .

**Table 1** Inversion of error free data. Hypocenter is the correct location, Start is the initial location, and the location is shown for the two following iterations. The rows give the hypocentral parameters ( $x$ ,  $y$ ,  $z$  and  $t_0$ ), the misfit  $e$  according to Equation (11) and the RMS value of the residuals.

|                       | Hypocenter | Start | 1. Iteration | 2. Iteration |
|-----------------------|------------|-------|--------------|--------------|
| x [km]                | 0.0        | 3.0   | -0.5         | 0.0          |
| y [km]                | 0.0        | 4.0   | -0.6         | 0.0          |
| z [km]                | 10.0       | 20.0  | 10.1         | 10.0         |
| $T_0$ [s]             | 0.0        | 2.0   | 0.2          | 0.0          |
| $e$ [s <sup>2</sup> ] |            | 94.2  | 0.6          | 0.0          |
| RMS [s]               |            | 3.1   | 0.25         | 0.0          |

Table 1 gives an example of locating an earthquake with 10 stations in a model with constant velocity (from Stein, 1991). The stations are between 11 and 50 km apart from the hypocenter. The earthquake has an origin time of 0 s at the point (0, 0, 10) km. The initial location is at (3, 4, 20) km at 2 s. The exact travel times were calculated using a velocity of 5 km/s and the iterations were done as indicated above. At the initial guess, the sum of the squared residuals was 92.4 s<sup>2</sup>, after the first iteration it was reduced to 0.6 s<sup>2</sup> and already at the second iteration; the ‘correct’ solution was obtained. This is hardly surprising, since the data had no errors. We shall later see how this works in the presence of errors.

### 3.3.4 Advanced methods

The problem of locating seismic events has during the last decade experienced a lot of attention and new procedures have been developed such as the double-difference location algorithm (Waldhauser and Ellsworth, 2000), a novel global differential evolution algorithm (Ružek and Kvasnička (2001), a probabilistic approach to location in 3-D and layered models by Lomax et al. (2000) as well as advanced grid search procedures to be applied in highly heterogeneous media (Lomax et al., 2001). Recent advances in travel-time calculations for three-dimensional structures complement these methods (e.g., Thurber and Kissling, 2000). Figure 5 shows how much the *precision* (or relative inter-event accuracy) of the locations within earthquake clusters can be improved by applying the above mentioned double-difference location algorithm. Several of these developments are summarized in a monograph edited by Thurber and Rabinowitz (2000), which also includes advances in global seismic event location procedures (Thurber and Engdahl, 2000).

**Figure 5** Examples of improving the ABCE locations for earthquake clusters (red dots) from regional networks of seismic stations (triangles) in China by relocating the events with the double-difference location algorithm (courtesy of Paul G. Richards).

A special volume about event location in context with the special requirements for monitoring the CTBT was published by Ringdal and Kennett (2001). During the IASPEI General Assembly in Santiago de Chile (2005) a workshop had been organized about the question how the ISC location procedures can be improved. Many contributions to this workshop were later published in a special volume (Schweitzer and Storchak, 2006).

## 4 Location errors

### 4.1 Error quantification and statistics

Since seismic events are located with arrival times that contain observational errors and the travel times are calculated under the wrong assumption that the exact model is known, all hypocenter determinations will have errors. Contouring the grid search RMS (Figure 4) gives an indication of the uncertainty of the epicenter. Likewise it would be possible to make 3-D contours to get an indication of the 3-D uncertainty. The question is now how to quantify this measure. The RMS of the final solution is very often used as a criterion for ‘goodness of fit’. Although it can be an indication, RMS depends on the number of stations and does not in itself give any indication of errors and RMS is not reported by, e.g., NEIC and ISC.

From Figure 4 it is seen that the contours of equal RMS are not circles. We can calculate contours within which there is a 67 % probability (or any other desired probability) of finding the epicenter (see below). We call this the error ellipse. This is the way hypocenter errors normally are represented. It is therefore not sufficient to give one number for the hypocenter error since it varies spatially. Standard catalogs from NEIC and ISC give the errors in latitude,

longitude and depth, which can also be very misleading unless the error ellipse has the minor and major axis NS or EW. In the example in Figure 4, this is not the case. Thus the only proper way to report error is to give the full specification of the error ellipsoid.

Before going into a slightly more formal discussion of errors, let us try to get a feeling for which elements affect the shape and size of the epicentral error ellipse. If we have no arrival time errors, there are no epicenter errors so the magnitude of the error (size of error ellipse) must be related to the arrival time uncertainties. If we assume that all arrival time reading errors are equal, only the size and not the shape of the error ellipse can be affected. So what would we expect to give the shape of the error ellipse? Figure 4 is an example of an elongated network with the epicenter off to one side. It is clear that in the NE direction, there is a good control of the epicenter since S-P times control the distances in this direction due to the elongation of the network. In the NW direction, the control is poor because of the small aperture of the network in this direction. We would therefore expect an error ellipse with the major axis NW as observed. Another way of understanding, why the error is larger in NW than it is in NE direction, is to look at Equation (12). The partial derivatives  $\partial T/\partial x$  will be much smaller than  $\partial T/\partial y$  so the  $\Delta y$ -terms will have a larger weight than the  $\Delta x$ -terms in the equations (strictly speaking the partial derivatives with respect to NW and NE). Consequently, errors in arrival times will affect  $\Delta x$  more than  $\Delta y$ . Note that if backazimuth observations were available for any of the stations far in the North or the South of the event, this would drastically reduce the error estimate in the EW direction since  $\partial \phi/\partial x$  is large while  $\partial \phi/\partial y$  is nearly zero.

Changing the geometry of the stations would give another shape of the error ellipse. It is thus possible for any network to predict the shape and orientation of the error ellipses, and given an arrival error, also the size of the ellipse for any desired epicenter location. This can, e.g., be used to predict how a change in network configuration would affect earthquake locations at a given site.

In all these discussions, it has been assumed that the errors have Gaussian distribution and that there are no systematic errors like clock errors. It is also assumed that there are no errors in the theoretical travel times, backazimuths, or ray parameter calculations due to unknown structures. This is of course not true in real life; however error calculations become too difficult if we do not assume a simple error distribution and that all stations have the same arrival time error. This means, however, that such error calculations give us only an idea about the “internal” precision of the locations within the model framework on which they are based. They should not be mistaken as being true location errors (see Section 7).

The previous discussion gave a qualitative description of the errors. We will now show how to calculate the actual hypocentral errors from the errors in the arrival times and the network configuration. The most common approach to seismic source location is based on the least squares inversion and a Gaussian distribution of the arrival time errors, in which case the statistics is well understood and we can use the Chi-Square probability density distribution to calculate errors. For a particular location,  $\chi^2$  can be calculated as:

$$\chi^2 = \frac{1}{\sigma^2} \sum_{i=1}^n r_i^2, \quad (19)$$

where  $\sigma$  is the assumed same standard deviation of any one of the residuals and  $n$  is the number of observations. We can now look at the standard statistical tables (extract in Table 2) to find the expected value of  $\chi^2$  within a given probability. As can be seen from the table, within 5% probability,  $\chi^2$  is approximately the number of degrees of freedom ( $ndf$ ), which in our case is  $n-4$ .

**Table 2** The percentage points of the  $\chi^2$  distribution for different numbers of degrees of freedom ( $ndf$ )

| $ndf$ | $\chi^2$ (95%) | $\chi^2$ (50%) | $\chi^2$ (5%) |
|-------|----------------|----------------|---------------|
| 5     | 1.1            | 4.4            | 11.1          |
| 10    | 3.9            | 9.3            | 18.3          |
| 20    | 10.9           | 19.3           | 31.4          |
| 50    | 34.8           | 49.3           | 67.5          |
| 100   | 77.9           | 99.3           | 124.3         |

If e.g., an event is located with 24 stations ( $ndf=20$ ), there is only a 5% chance that  $\chi^2$  will exceed 31.4. The value of  $\chi^2$  will grow as we move away from the best fitting epicenter and in the example above, the contour within which  $\chi^2$  is less than 31.4 will show the error ellipse within which there is a 95 % chance of finding the epicenter. In practice, errors are mostly reported within 67 % probability, which mean with  $\pm 1$  standard deviation.

The errors in the hypocenter and origin time can also formally be defined with the variance – covariance matrix  $\sigma_X^2$  of the hypocentral parameters. This matrix is defined as

$$\sigma_X^2 = \begin{Bmatrix} \sigma_{xx}^2 & \sigma_{xy}^2 & \sigma_{xz}^2 & \sigma_{xt}^2 \\ \sigma_{yx}^2 & \sigma_{yy}^2 & \sigma_{yz}^2 & \sigma_{yt}^2 \\ \sigma_{zx}^2 & \sigma_{zy}^2 & \sigma_{zz}^2 & \sigma_{zt}^2 \\ \sigma_{tx}^2 & \sigma_{ty}^2 & \sigma_{tz}^2 & \sigma_{tt}^2 \end{Bmatrix}. \quad (20)$$

The diagonal elements are variances of the location parameters  $x$ ,  $y$ ,  $z$  and  $t_0$  while the off diagonal elements give the coupling between the errors in the different hypocentral parameters. For more details, see e.g., Stein (1991). The nice property about  $\sigma_X^2$  is that it is simple to calculate:

$$\sigma_X^2 = \sigma^2 * (G^T G)^{-1}, \quad (21)$$

where  $\sigma^2$  is the variance of the arrival times multiplied by the identity matrix and  $G^T$  is  $G$  transposed. The standard deviations of the hypocentral parameters are thus given by the square root of the diagonal elements and these are the usual errors reported. So how can we use the off diagonal elements? Since  $\sigma_X^2$  is a symmetric matrix, a diagonal matrix in a coordinate system, which is rotated relatively to the reference system, can represent it. We now only have the errors in the hypocentral parameters, and the error ellipse simply have semi axes  $\sigma_{xx}$ ,  $\sigma_{yy}$ , and  $\sigma_{zz}$ . The main interpretation of the off diagonal elements is thus that they define the orientation and shape of the error ellipse. A complete definition therefore requires 6 elements. Eqs. (20) and (21) also show, as stated intuitively earlier, that the shape and

orientation of the error ellipse depends only on the geometry of the network and the crustal structure whereas the standard deviation of the observations is a scaling factor as long they are equal for all observations.

The critical variable in the error analysis is therefore the arrival-time variance  $\sigma^2$ . This value is usually larger than it would be expected from timing and picking errors alone, however it might vary from case to case. Setting a fixed value for a given data set could result in unrealistic error calculations. Most location programs will therefore estimate  $\sigma$  from the residuals of the best fitting hypocenter:

$$\sigma^2 = \frac{1}{ndf} \sum_{i=1}^n r_i^2. \quad (22)$$

Division by  $ndf$  rather than by  $n$  compensates for the improvement in fit resulting from the use of the arrival times from the data. However, this only partly works and some programs allow setting an a priori value which is used only if the number of observations is small. For small networks this can be a critical parameter.

Recently, some studies (e.g., Di Giovambattista and Barba, 1997; Parolai et al., 2001) showed, both for regional and local seismic networks, that the error estimates ERH (in horizontal) and ERZ (in vertical direction), as given by routine location programs (e.g., in HYPOELLIPSE (Lahr, 1989 and 2003)) cannot be considered as a conservative estimate of the true location error and might lead investigators to unjustified tectonic conclusions (see also Figures 11 and 12).

## 4.2 Example of error calculation

We can use the previous error free example (see Table 1) and add some errors (from Stein, 1991). We add Gaussian errors with a mean of zero and a standard deviation of 0.1 s to the arrival times. Now the data are inconsistent and cannot fit exactly. As it can be seen from the results in Table 3, the inversion now requires 3 iterations (2 before) before the locations stop changing. The final location is not exactly the location used to generate the arrival times and the deviation from the correct solution is 0.2, 0.4, and 2.2 km for x, y, and z respectively, and 0.2 s for the origin time. This gives an indication of the location errors.

It is now interesting to compare what is obtained with the formal error calculation. Table 4 gives the variance – covariance matrix. Taking the square root of the diagonal elements we get the standard deviations of x, y, z and  $t_0$  as 0.3, 0.3 and 1.1 km and 0.1 s, respectively. This is close to the ‘true’ error so the solution is quite acceptable. Also note that the RMS is close to the standard error.

**Table 3** Inversion of arrival times with a 0.1 s standard error. As in Table 1, hypocenter is the correct location, Start is the initial location, and the locations are shown after the three following iterations. e is the misfit according to Equation (11).

|        | Hypocenter | Start | 1. Iteration | 2. Iteration | 3. Iteration |
|--------|------------|-------|--------------|--------------|--------------|
| x [km] | 0.0        | 3.0   | -0.2         | 0.2          | 0.2          |
| y [km] | 0.0        | 4.0   | -0.9         | -0.4         | -0.4         |

|                     |      |      |      |      |      |
|---------------------|------|------|------|------|------|
| z [km]              | 10.0 | 20.0 | 12.2 | 12.2 | 12.2 |
| t <sub>0</sub> [s]  | 0.0  | 2.0  | 0.0  | -0.2 | -0.2 |
| e [s <sup>2</sup> ] |      | 93.7 | 0.33 | 0.04 | 0.04 |
| RMS [s]             |      | 3.1  | 0.25 | 0.06 | 0.06 |

**Table 4** Variance – covariance matrix for the example in Table 3.

|   | x    | y     | z     | t     |
|---|------|-------|-------|-------|
| x | 0.06 | 0.01  | 0.01  | 0.00  |
| y | 0.01 | 0.08  | -0.13 | 0.01  |
| z | 0.01 | -0.13 | 1.16  | -0.08 |
| t | 0.00 | 0.01  | -0.08 | 0.0   |

The variance – covariance matrix shows some interesting features. As seen from the diagonal elements of the variance – covariance matrix, the error is much larger in the depth estimate than in x and y. This clearly reflects that the depth is less well constrained than the epicenter which is quite common unless there are stations very close to the epicenter and thus  $|(\mathbf{d}-\Delta)| / \Delta \gg 1$ . For simplicity, we have calculated the standard deviations from the diagonal terms, however since the off diagonal terms are not zero, the true errors are larger. In this example it can be shown that the semi-major and semi-minor axis of the error ellipse have lengths of 0.29 and 0.24 km respectively, and the semi-major axis trends N22°E, so the difference from the original diagonal terms is small.

The z,t or (t,z) term, the covariance between depth and origin time, is negative, indicating a negative trade-off between the focal depth and the origin time; an earlier source time can be compensated by a larger source depth and vice versa. This is commonly observed in practice and is more prone to happen if only first P-phase arrivals are used such that there is no strong control of the source depth by P times measured at different distances.

Error calculation is a fine art, there are endless variations on how it is done and different location programs will usually give different results.

## 5 Relative location methods

### 5.1 Master event technique

The relative location between events within a certain region can often be made with a much greater accuracy than the absolute location of any of the events. This is the case when velocity variations outside the local region are the major cause of the travel-time residuals such that residuals measured at distant stations will be very similar for all of the local events. Usually, the events in the local area are relocated relative to one particularly well-located event, which is then called the **master event**.

Since Gutenberg and Richter (1937), hypocenters of closely located events have been estimated relatively to each other by choosing one of them as a master event. Later, algorithms were developed to solve the problem for larger sets of events in one common

inversion scheme (e.g., Douglas, 1967; Evernden, 1969; Dewey, 1972; Dewy and Algermissen, 1974). Today, many program packages can be found that locate large sets of events more or less closely spaced together, based on different solution strategies (e.g., Kissling et al., 1994; Pujol, 2000; Waldhauser and Ellsworth, 2000) depending on the availability of data types and research interests. It should be mentioned that the Master Event Technique can only be used when the distance to the stations is much larger than the distance between the events.

Most location programs can be used for a master event location. For this travel-time anomalies outside the source region are assumed to cause all individual station residuals after the location of the master event. By using these station residuals as station corrections, the location of the remaining events will be made relative to the master event since all relative changes in arrival times are now entirely due to changes in location within the source region. It is obvious that only stations and phases for which observations are available for the master event can be used for the remaining events. Ideally, the same combination of stations and phases should be used for all events.

## 5.2 Joint hypocenter location

In the Master Event Technique, it was assumed that true structure dependent residuals could be obtained absolutely correct from the master event, however, other errors could be present in the readings for the master event itself. A better way is to determine the most precise station residuals using the whole data set. This is what Joint Hypocenter Determination (JHD) is about (Douglas, 1967, Pujol, 2000; 2003). Instead of determining one hypocenter and origin time, we will jointly determine  $m$  hypocenters and origin times, and  $n$  station corrections. This is done by adding the station residuals  $\Delta t_i^s$  to Equation (13) and writing the equations for all  $m$  events (index  $j$ ):

$$r_{ij} = (\partial T / \partial x_{ij}) * \Delta x + (\partial T / \partial y_{ij}) * \Delta y + (\partial T / \partial z_{ij}) * \Delta z + \Delta t_i^s + \Delta t_j. \quad (23)$$

The first to propose the JHD method was Douglas (1967). Since the matrix  $\mathbf{G}$  of Equation (14) is now much larger than the  $4 \times 4$  matrix for a single event location, efficient inversion schemes must be used. If we use e.g., 20 stations with 2 phases each for 10 events, there will be  $20 * 10 * 2 = 400$  equations and 80 unknowns (10 hypocenters and origin times, and 20 station residuals).

The relative locations obtained by the Master Event Technique or the JHD are usually more reliable than individually estimated relative locations. However, only if we have the absolute location of one of the events (e.g., a known explosion), we will be able to convert the relative locations of a Master Event algorithm into absolute locations, whereas for the JHD “absolute” locations are obtained for all events if the assumed velocity model is correct. Accurate relative locations are useful to study, e.g., the structure of a subduction zone or the geometry of an aftershocks area, which might indicate the orientation and geometry of the fault. Pujol (2000) has given a very detailed outline of the method and its application to data from local seismic networks. Figure 6 shows an example for increased location accuracy after applying JHD.

**Figure 6** Comparison of earthquake locations using the normal procedure at ISC (left) and JHD relocations (right). The events are located in the Kurile subduction zone along the rupture zones of large thrust events in 1963 and 1958. The vertical cross sections shown traverse the thrust zone from left to right. Note that the JHD solutions reduce the scatter and make it possible to define a dipping plane (from Schwartz et al., 1989).

## 6 Practical consideration in seismic source locations

This section is intended to give some practical hints on seismic source location. Different location programs, in particular for observations at local and regional distances, have been developed and are in use since many years (e.g., HYPO71 (Lee and Lahr, 1975; Lee et al., 2003), HYPOINVERSE (Klein, 1978; 1985, 2002, 2003), HYPOELLIPSE (Lahr, 1982; 2003)). This Section does not refer to any particular location program, but most of the parameters discussed can be used with the programs HYPOCENTER (Lienert et al., 1988; Lienert, 1991; Lienert and Havskov, 1995) or HYPOSAT (Schweitzer, 2001, see also PD 11.1), which can locate seismic sources at local, regional and teleseismic distances.

### 6.1 Seismic phases

For the IASPEI recommended seismic phase-naming conventions see IS 2.1 or Storchak et al. (2003). The most unambiguous seismic phase to pick is usually the first P phase. Such P phases are the main phase observations used for most teleseismic locations. For seismic events at local and regional distances, usually S phases are also used. Using phases with different seismic velocities and/or slownesses has the effect of better constraining the distances and there is then less trade-off between depth and origin time or epicenter location and origin time if the epicenter is outside the network. The focal depth is best controlled (with no trade-off between depth and origin time) when seismic phases are included in the location procedure, which have a different sign of the partial derivative  $\partial T/\partial z$  in Equation (13) such as for very locally observed direct up-going Pg (positive) and Pn (negative) (see Section 6.3 Hypocentral depth and Figure 9). In general, it is thus an advantage to use as many different phases as possible under the assumption that they are correctly identified. Schöffel and Das (1999) gave a striking example (see Figure 7). But one very wrong phase can throw off an

otherwise well constrained solution. This highlights the crucial importance of the capability of the observatory personnel to recognize and report such phases during their routine seismogram analysis.

**Figure 7** Examples of significant improvement of hypocenter location for teleseismic events by including secondary phases. Left: hypocenter locations using only P phases; middle: by including S phases; right: by including also depth phases and core reflections with a different sign of  $\partial T/\partial z$  (modified from Schöffel and Das, *J. Geophys. Res.*, Vol. 104, No. B6, page 13, Figure 2; © 1999, by permission of American Geophysical Union).

Engdahl et al. (1998) used the entire ISC database to relocate more than 100,000 seismic events. They used not only a new scheme to associate correctly secondary phases, they also systematically searched for pwP onsets in the case of subduction-zone events to get better depth estimates, and they used a more modern global Earth model (AK135) to avoid the known problems with the Jeffreys-Bullen tables (Jeffreys and Bullen, 1940; 1948; 1958; 1967; 1970). With all these changes the authors reached a far more consistent distribution of hypocenters (in particular for subduction zones) and sharper picture of global seismicity. From data year 2006 on, the ISC is using model AK135 instead of the Jeffreys-Bullen tables in its bulletin productions.

The majority of location programs for local earthquakes use only first arrivals (e.g., HYPO71, Lee and Lahr, 1975). This is good enough for many cases. In some distance ranges, Pn is the first arrival, and it usually has small amplitudes. This means that the corresponding Sn phase, which is then automatically used by the program, might have also very small amplitudes and is not recognized, while actually the phase read is Sg or Lg instead. Since the program automatically assumes a first arrival, a wrong travel-time curve is used for the observed phase, resulting in a systematic location error. This error is amplified by the fact that the S phase, due to its low velocity, has a larger influence on the location than the P phase. It is therefore important to use location programs where all crustal phases can be specified.

Schweitzer (2001) developed an enhanced routine to locate both local/regional and teleseismic events, called HYPOSAT. The program runs with global Earth models and user defined horizontally layered local or regional models with layers of arbitrary velocity gradients. It provides the best possible hypocenter estimates of seismic sources by using travel-time differences between the various observed phases besides the usual input parameters such as arrival times of first and later onsets (complemented by backazimuth and ray parameters in the case of array data or polarization analyses). If S observations are also

available, preliminary origin times are estimated by using the Wadati approach (see Figure 3 in Section 3.2). An initial epicenter with a priori uncertainties can be estimated by calculating the intersection of all backazimuth observations. By relocating events with real data Schweitzer could show that HYPOSAT solutions have the smallest errors when, besides the absolute onset times the travel-time differences of all available primary and secondary phase readings are also taken into account. The most advanced version of HYPOSAT can be downloaded for free either directly from the program list in the NMSOP-2 cover page folder *Download Programs & Files* or from NORSAR's anonymous ftp-server <ftp://ftp.norsar.no/pub/outgoing/johannes/hyposat/> and a detailed program description is given in PD 11.1.

## 6.2 Initial location

Iterative location programs often start with an initial location at a point near the station recording the earliest arrival. This is good enough for most cases, particularly when the station coverage is good and the epicenter is near or within the network. However, this can also lead to problems when using least squares techniques, which converge slowly or sometimes not at all for events outside the limits of a regional network (Buland, 1976). Another possibility is that the solution converges to a local minimum, which might be far from the correct solution. For small-elongated networks, two potential solutions may exist at equal distances from the long axis. An initial location close to the station with the earliest arrival can then bias the final solution to the corresponding side of such a network. Although this bias usually is on the correct side, any systematic error in the earliest-arrival station's time can have a disproportionately strong effect on the final location. Thus in many cases, it is desirable to use a better start location than the nearest station. There are several possibilities:

- a) in many cases the analyst knows by experience the approximate location and can then manually give an initial location; most programs have this option;
- b) similar phases at different stations can be used to determine the apparent velocity and backazimuth of a plane wave using linear regression on the arrival times (e.g., using the network as a seismic array, see Chapter 9). With apparent velocity and/or S-P times, an estimate of the initial location can be made. This method is particularly useful when locating events far away from the network (regionally or globally);
- c) backazimuth information is frequently available from 3-component stations or seismic arrays and can be used as under b);
- d) if backazimuth observations are available from different stations, an initial epicenter can be determined by calculating the intersection of all backazimuth observations;
- e) S-P and the circle method can be used with pairs of stations to get an initial location;
- f) the Wadati approach can be used to determine an initial source time.

The initial depth is usually a fixed parameter and set to the most likely depth for the region. For local earthquakes usually a depth range of 10-20 km is used, while for distant events, the initial depth was often set to 33 km, which is the crustal thickness in the Jeffreys-Bullen spherical Earth model. If depth phases, e.g., pP are available for distant events, these phases can be used to set or fix the depth (see next section).

## 6.3 Hypocentral depth

The hypocentral depth is the most difficult parameter to determine due to the fact that the travel-time derivative with respect to depth changes very slowly as function of depth (see Figure 8) unless the station is very close to the epicenter. In other words, the depth can be moved up and down without changing the travel time much. Figure 8 shows a shallow (ray 1) and a deeper event (ray 2). It is clear that the travel-time derivative with respect to depth is nearly zero for ray 1 but not for ray 2. In this example, it would thus be possible to get a depth estimate for the deeper event but not for the shallower one. Unfortunately, at larger distances from the source, most rays are more like ray 1 than ray 2 and locations are therefore often made with a fixed ‘normal’ start depth. Only after a reliable epicenter is obtained will the program try to iterate for the depth. Another possibility is to locate the event with several initial depths and then use the depth that gives the best fit to the data. Although one depth will give a best fit to all data, the depth estimate might still be very uncertain and the error estimate must be checked.

**Figure 8** The depth – distance trade off in the determination of focal depth.

For teleseismic events, the best way to improve the depth determination is to include readings from the so-called depth phases (e.g., Gutenberg and Richter, 1936 and 1937; Engdahl et al., 1998) such as pP, pwP (reflection from the ocean free surface), sP, sS or similar but also reflections from the Earth's core like PcP, ScP or ScS (see Figure 7). The travel-time differences (i.e., depth phase-direct phase) as pP-P, sP-P, sS-S and pS-S are quite constant over a large range of epicentral distances for a given depth so that the depth can be determined nearly independently of the epicentral distance. Another way of getting a reliable depth estimate for teleseismic locations is to have both near and far stations available. In particular, event observations from local and regional stations together with PKP observations have been used together for this purpose. However, this is unfortunately not possible for many source regions and small magnitude events.

For local events, a rule of thumb is that at least several near stations should not be further away than 2 times the depth in order to get a reliable estimate (Figure 8). This is very often not possible, particularly for regional events. At a distance of more than  $2 \times \text{depth}$ , the depth-depending partial derivative changes very little with depth if the first arriving phase is the more or less horizontally propagating Pg. But at distances where the critically refracted (so-called head-waves) Pb or Pn arrive, there is again some sensitivity to depth due to the more steeply down going rays of Pb or Pn (Figure 9) and because of the different sign of the partial derivatives of their travel times with depth, which is negative for Pn and positive for Pg. Thus, if stations are available at distances where both direct and refracted rays are first arrivals, reasonably reliable depth solutions might be obtained. An even better result one gets when both Pg and Pn arrivals can reliably be picked at the same station. The accuracy of [the](#)

hypocenter location is then comparable to using P and pP for teleseismic events. Yet, correct identification of secondary P phases is often difficult and a wrong identification might make matters worse.

**Figure 9** Example of both Pg and Pn rays in a simplified, single layer crustal model.

The depth estimate using a layered crustal model remains problematic even with a mix of phases. In checking catalogs with local earthquakes, it will often be noted that there is a clustering of hypocenters at layer boundaries. This is caused by the discontinuities in the travel-time curves of the direct phase Pg as a function of depth at layer boundaries (see Figure 10 as an example). The Pg-travel time suddenly decreases when the hypocenter crosses a boundary (here Moho) since a larger part of the ray suddenly is in a higher velocity layer, while the Pn-travel time continuously decreases as the depth increases as long as the event is still within the crust. This gives rise to the discontinuities in the Pg-Pn travel-time curve. So one Pn-Pg travel-time difference is not enough to ensure a reliable depth estimate, several such phase arrivals must be available.

**Figure 10** Simplified two-layer crustal model of ray paths of Pg and Pn phases (left). On the right-hand panel the travel-time difference Pg-Pn as a function of depth is qualitatively sketched. It is assumed that the distance is large enough for Pn to be the first arrival.

Even when several Pg, Pb (very seldom) and Pn phases are available, depth estimates still remain a problem at regional distances due to the uncertainty in the crustal models. Since the depth estimates critically depend on accurate travel-time calculations for these phases, small model uncertainties can quickly throw off the depth estimate.

Many location programs give the RMS of the travel-time residuals in a grid around the calculated hypocenter. In addition to the error estimates, this gives an idea about the accuracy and thus a local minimum might be found. A more direct way of estimating the quality of the depth estimate is to calculate the RMS as a function of depth in order to check if a local

minimum has been reached. This is particularly relevant for crustal earthquakes at shallow depth and can also be used as a complementary tool for discriminating better between quarry blasts and earthquakes.

## 6.4 Outliers and weighting schemes

The largest residuals have a disproportionately large influence on the fit of the arrival times due to the commonly used least squares fit. Most location programs will have some kind of residual weighting scheme in which observations with large residuals are given lower or even no weight. Bisquare weighting is often used for teleseismic events (Anderson, 1982). The residual weighting works very well if the residuals are not extreme since the residual weighting can only be used after a few iterations when the residuals are already close to the final ones. Individual large residuals can often lead to completely wrong solutions, even when 90% of the data are good; residual weighting will not help in these cases. Some programs will try to scan the data for gross errors (like minute errors) before starting the iterative procedure. If an event has large residuals, try to look for obvious outliers. A Wadati diagram can often help in spotting bad readings for local events (see Figure 3 in Section 6.2).

The arrival-time observations by default will always have different weights in the inversion. A simple case is that S waves may have larger weights than P waves due to their lower velocities. An extreme case is the T wave (a guided wave in the ocean), which with its low velocity (1.5 km/s) can completely dominate the solution. Considering that the accuracy of the picks is probably best for the P waves, it should be natural that P arrivals have more importance than S arrivals in the location. However, the default parameter setting in most location programs is to leave the original weights unless the user actively changes them. It is normally possible to give *a priori* for all S phases a lower weight and in addition, all phases can be given individual weights, including being totally weighted out.

When working with local seismic sources, the nearest stations will usually provide the most accurate information due to the clarity of the phases. In addition, uncertainty in the local model has less influence on the results at short distances than at large distances; this is particularly true for the depth estimate. It is therefore desirable to put more weight on data from near stations than on those from distant stations and this is usually done by using a distance weighting function of

$$w_d = \frac{x_{far} - \Delta}{x_{far} - x_{near}}, \quad (24)$$

where  $\Delta$  is the epicentral distance,  $x_{near}$  is the distance to which full weight is used and  $x_{far}$  is the distance where the weight is set to zero (or reduced). The constants  $x_{near}$  and  $x_{far}$  are adjusted to fit the size of the network;  $x_{near}$  should be about the diameter of the network, and  $x_{far}$  about twice  $x_{near}$ . For a dense network,  $x_{near}$  and  $x_{far}$  might be made even smaller for more accurate solutions.

## 6.5 Ellipticity of the Earth

Until now we only assumed that the model used for calculating distances or travel times is either a flat model for local or regional events or a standard spherical model of the Earth for teleseismic events. However, the Earth is neither a sphere nor a flat disk but an ellipsoid symmetrical to its rotation axis. It was Gutenberg and Richter (1933) who first pointed out that the difference between a sphere and an ellipsoid must be taken into account when calculating epicentral distances and consequently also the travel times of seismic phases. Therefore, they proposed the usage of geocentric coordinates instead of geographic coordinates to calculate distances and angles on the Earth. Because of the axially symmetrical figure of the Earth, the geocentric longitude is identical to the geographic longitude. To convert a geographic latitude  $lat_g$  into a geocentric latitude  $lat_c$  one can use the following formula:

$$lat_c = \arctan((1 - (6378.136 - 6356.751) / 6378.136)^2 * \tan lat_g). \quad (25)$$

With this formula all station latitudes have to be converted before an event location and after the inversion, the resulting geocentric event latitude has to be converted back by applying the inverse equation

$$lat_g = \arctan(\tan lat_c / (1 - (6378.136 - 6356.751) / 6378.136)^2). \quad (26)$$

With this procedure all angle calculations related to an event location are done for a sphere. The calculated distances are measured in degrees and to convert them into km, one has to use the local Earth radius  $R_{loc}$ :

$$R_{loc} = \sqrt{(6378.136 * \cos lat_c)^2 + (6356.751 * \sin lat_c)^2}. \quad (27)$$

This value has then to be applied for converting a distance  $D$  measured in degrees into a distance measured in km, or vice versa:

$$D[km] = \frac{2\pi * R_{loc}}{360} * D[deg] \quad \text{or} \quad D[deg] = \frac{360}{2\pi * R_{loc}} * D[km] \quad (28)$$

All standard Earth models are defined for a spherically symmetrical Earth with a mean radius of 6371 km. Therefore the standard tables also contain travel times calculated for a sphere. Bullen (1937, 1938, 1939) was the first to calculate latitude-depending travel-time corrections (ellipticity corrections) to be used together with travel-time tables for a spherical Earth. Later work on this topic was done by Dziewonski and Gilbert (1976) and Dornboos (1988b). Kennett and Gudmundsson (1996) published a set of ellipticity corrections for a large number of seismic phases calculated applying the spherical Earth model AK135.

In conclusion: to get the theoretical travel time for an event in teleseismic or regional distance, one has first to calculate the geocentric epicentral distance, then use travel-time tables as calculated for a spherical Earth model, and finally apply the latitude (event and station!) dependent ellipticity correction. Most location routines automatically apply the described methods and formulas but it is important to check this in detail and eventually to change a location program.

## 6.6 Importance of the velocity model

In this context the importance of the model assumptions underlying the location procedure has to be emphasized. The chosen 1-D regional velocity model has a strong influence on the location of seismic sources (e.g., Kennett, 1992) and many studies have shown (e.g., Kissling, 1988) that the accuracy of locating hypocenters can even be more improved by using station corrections in addition to a well-constrained global 1-D velocity. However, Spallarossa et al. (2001) showed that in strongly heterogeneous local areas even a 1-D model with station corrections does not significantly improve the accuracy of the location parameters. High-precision location in such cases can only be achieved by using a 3-D model. This is particularly true for locating earthquakes in volcanic areas (see Lomax et al., 2001).

Smith and Ekström (1996) investigated the improvement of teleseismic event locations by using a 3-D Earth model. They came to the conclusion that it “... offers improvement in event locations over all three 1-D models with, or without, station corrections.” For the explosion events, the average mislocation distance is reduced by approximately 40%; for the earthquakes, the improvements are smaller. Corrections for crustal thickness beneath source and receiver are found to be of similar magnitude to the mantle corrections, but use of station corrections together with the 3-D mantle model provide the best locations. Also Chen and Willemann (2001) carried out a global test of seismic event locations using 3-D Earth models. Although a tighter clustering of earthquakes in subduction zones was achieved by using a 3-D model rather than using depth from the ISC Bulletin based on 1-D model calculations, they concluded that the clustering was not as tight as for depths computed by Engdahl et al. (1998) who used depth phases as well as direct phases. Thus, even using the best available global 3-D models can not compensate for the non-use of depth phases and core reflections in teleseismic hypocenter location (see Figure 7).

An example case for the improved location of local earthquakes is given in Figures 11 and 12. The upper panel in Figure 11 shows the initial epicenter locations of aftershocks of the Cariaco earthquake ( $M_s = 6.8$ ) on July 9, 1997 in NE Venezuela based on an averaged 1-D crustal velocity model. The mean location error (i.e., the calculated *precision* with respect to the assumed model) was about 900 m. On average, the aftershocks epicenters occurred about 2 to 3 km north of the surface fault trace.

**Figure 11** Epicentral distribution of aftershocks of the Cariaco earthquake ( $M_s=6.8$ ) on July 9, 1997 in NE Venezuela. Top: results from HYPO71 based on a one-dimensional velocity-depth distribution. Bottom: Relocation of the aftershocks on the basis of a 3-D model derived from a tomographic study of the aftershock region (courtesy of M. Baumbach () H. Grosser and A. Rietbrock).

A detailed tomographic study revealed lateral velocity contrasts of up to 20% with higher velocities towards the north of the El Pilar fault (Figure 12). Relocating the events with the 3-D velocity model the epicenters were systematically shifted southward by about 2 km and now their majority aligned rather well with fault traces mapped before the earthquake as well as with newly ruptured fault traces (Figure 11, lower panel). Also in the cross sections the data scatter was clearly reduced so that closely spaced outcropping surface faults could be traced down to a depth of more than 10 km. These results point to the fact that in the presence of lateral velocity inhomogeneities epicenter locations are systematically displaced in the direction of higher velocities. We will look into this problem more closely in Section 7.

**Figure 12** 3-D distribution of the P-wave velocity in the focal region of the 1997 Cariaco earthquake as derived from a tomographic study. The horizontal section shows the velocity distribution in the layer between 2 km and 4 km depth. Red and blue dots mark the epicenters of the aftershocks. The red ones were chosen because of their suitability for the tomography. The six vertical cross sections show depth distributions of the aftershocks (green dots) together with the deviations of the P-wave velocity from the average reference model. The depth range and the lateral changes of fault dip are obvious (courtesy of M. Baumbach<sup>(†)</sup>, H. Grosse and A. Rietbrock).

## 7 Internal and external (real) accuracy of locations

For decades the international data centers have located earthquakes world-wide by means of the 1-D Jeffreys-Bullen velocity model of the Earth and Jeffreys-Bullen travel-time tables (Jeffreys and Bullen, 1940; 1948; 1958; 1967; 1970) without external control of the accuracy of such solutions by independently checking them with similarly strong events of exactly known position and origin time. Therefore, the question has remained open for a long time as to whether these calculated location errors were real or just the minimized average errors for the best fitting solutions to the observed data based on model assumptions with respect to the validity of the velocity model, the non-correlation of the various parameters to be determined and the Gaussian distribution of both the model errors and the data reading errors. If the latter is the case then the calculated errors are no measure of the real accuracy of the calculated location and origin time but rather a measure of the internal precision of fitting best the data to the used model.

In order to investigate this in more detail, Bormann (1972a and b) looked into the travel-time errors reported by the international data centers for the German seismological observatory Moxa (MOX) for earthquakes in different regions of the world. As an example, he got for the same data set of events from the Kurile Islands the mean residual  $\bar{\delta}t_p = + 0.16$  s and a standard deviation  $\sigma = \pm 0.65$  s when referring the MOX onset-time readings to the locations

published by the U.S. Coastal and Geodetic Survey (USCGS, World Data Center A, WDC A) and  $\bar{\delta}t_p = +0.35$  s with  $\sigma = \pm 1.1$  s when referring to the locations published by the Academy of Sciences of the Soviet Union (ANUSSR, World Data Center B, WDC B) which used the same Jeffreys-Bullen travel-time tables as the USCGS. Thus, the travel-time (or onset-time reading) errors calculated by the data centers for seismic stations are not real errors of these stations or their readings but depend on the number and distribution of stations used by these centers in their location procedure. And these were rather different for WDC A and WDC B. While the USCGS used the data of a worldwide station network, ANUSSR based its locations on the station network of the former Soviet Union and East European countries and these “looked at” events outside Eurasia from a much narrower azimuth and distance range. But this is equivalent to the discussion related to Figure 4. Although the mean station residuals calculated by these two data centers for the considered region were not significantly different and not far from zero, their systematic mislocations with respect to “ground truth” locations such as those of underground nuclear explosions (Herrin and Taggart, 1968; Bormann, 1972a; Engdahl et al., 1998) reached in subduction zones with large lateral velocity inhomogeneities several 10 km and were larger for the network with a limited azimuthal coverage. Therefore, the ISC waits for one to two years before running its final location procedure. This allows collecting as many seismic phase readings as possible from worldwide distributed seismological observatories and thus assures the best geographic coverage for each seismic event.

What is the reason for this systematic mislocation, which usually remains unrecognized unless one locates strong independently controlled sources of exactly known source parameters and origin time? Figure 13 shows some hypothetical earthquakes at different depth on a vertically dipping fault. It separates two half-spaces with different wave propagation velocity  $v_2 > v_1$ . This is a realistic model for parts of the San Andreas Fault. The lateral velocity difference across the fault may be as large as 5 to 7 %. S1 and S2 may be two stations at the same hypocentral distances from the events. But because of  $v_2 > v_1$  the onset time  $t_2$  at S2 is earlier (travel-time shorter) than for  $t_1$  at S1. Running the location procedure with the common residual minimization on the assumption of a laterally homogeneous velocity model will result in hypocentral distances  $d_2(h) < d_1(h)$ . Since the difference increases with depth, the hypocenters are not only offset from the real fault but seem to mark even a slightly inclined fault, which is not the case.

**Figure 13** Illustration of the systematic mislocation of earthquakes along a fault with strong lateral velocity contrast.  $v_0$  is the assumed model velocity with  $v_2 > v_0 > v_1$ .

From this hypothetical example we learn that locations based on 1-D velocity models in the presence of 2-D or 3-D velocity inhomogeneities will be systematically shifted in the direction of increasing velocities (or velocity gradients), the more so, the less the station distribution controls the event from all azimuths. This is precisely the cause for the above mentioned larger systematic mislocations of WDC B as compared to WDC A. While the latter localizes events using data from a global network, the former used solely data from the former Soviet and East European territory, i.e., stations which view the Aleutian Islands from only a narrow azimuth range. The direction of systematic mislocation of both centers to the NW agrees with the NW directed subduction of the Pacific plate underneath the Aleutians. According to Jacob (1972) this cold lithospheric plate has 7 to 10% higher P-wave velocities than the surrounding mantle. A study by Lienert (1997) also addresses this problem of assessing the reliability of seismic event locations by using known nuclear tests.

The above discussion illustrates that we have to differentiate between the *precision* and the *accuracy* of locations (for definition of these terms see also the Glossary) and highlights the utmost importance of the general availability and easy accessibility of so-called seismic reference events with very well known hypocenter coordinates and origin time. They are needed for tomographic studies, the derivation of improved local, regional and global velocity models, the calibration and quality assessment of seismic network and array location procedures and other related issues. Such events may be chemical or nuclear underground explosions, which are commonly known exactly, or earthquakes that have been precisely located by available dense local networks. Such reference events can be considered as independent “ground truth” (GT) data. They are classified according to the accuracy with which the event coordinates are known in terms of integer values of kilometer (GT0, GT1, GT2, GT5, GT10). GT0 to GT2 data are available only for chemical and underground nuclear explosions, GT5 and larger mostly for earthquakes.

For many years the IASPEI Commission on Seismic Observation and Interpretation (CoSOI) had entrusted a Working Group with the elaboration of guidelines for the identification, collection and quality assessment as well as the initial compilation of a world-wide listing of such events. Meanwhile, the International Seismological Centre (ISC) has established a website data base of reference earthquakes and explosions for which hypocenter information is known with high confidence and which were associated with seismic signals that have been recorded at regional and/or teleseismic distances (see <http://www.isc.ac.uk/GT/index.html> ). On this website one finds the actual global IASPEI Reference Event List and map. As of summer 2011 it comprised the following numbers of GT events: GT0 – 650, GT1 – 367, GT2 – 123, GT5 – 6195 (out of which about 6000 are earthquakes). Through this website one can also submit new information about reference events. IASPEI encourages the scientific community to submit to the ISC such reference event information using the IASPEI developed guidelines for identifying candidate events and assessing their quality.

How to identify and collect such ground truth events is described in detail in IS 8.6, and IS 8.5 gives more details about the criteria for assessing the accuracy and reliability of locations depending on the geometry and azimuthal distribution of reporting stations, specifically about the GT5 criteria at 90% and 95% confidence level for local networks as defined by Engdahl et al. (2001), Bondar et al. (2004), and Bondár and McLaughlin (2009), respectively. These criteria are now operationally applied in the authoritative location scheme of the European-Mediterranean Seismological Centre (EMSC; <http://www.emsc-csem.org>) and its real time information services. In this scheme locations are considered to be accurate when they fulfill the GT5 criteria and additionally as reliable if they can be reproduced to within 15 km when

applying different location procedures and velocity models to the same data set. To expect more accurate routine earthquake locations based on regional and common local network data is hardly realistic for earthquakes with magnitudes below 6 and questionable anyway for earthquakes with magnitudes above 7 and thus linear rupture dimensions ranging from several 10 to several 100 kilometers.

## Acknowledgments

Some of the preceding text has followed a similar description in Shearer (1999). Several figures and ideas have also been taken from Stein (1991), Lay and Wallace (1995), Schöffel and Das (1999). Thanks go to M. Baumbach, H. Grosser and A. Rietbrock for making Figures 11 and 12 available and to R. E. Engdahl for critical proof reading and valuable suggestions which helped to improve the text and to complement the references.

## 1 General information

The results of seismogram analyses are published in reports, event lists, bulletins and data catalogues (called "products"), which are the basis of data exchange between seismological institutions, data centers and for informing the public. The parameter data, primarily source and/or phase parameter values, should be stored in a digital database and presented in a clear and uniform manner.

The predefinition of an appropriate format depends on the requirements for the major usage of the product, for example whether a product is intended for further applications on a computer or for human readability. However, earthquake catalogues are published in numerous different formats. Therefore, a description of the individual used format should be given as a reference or directly attached to the product. Some formats have been developed to a comprehensive level, which is widely accepted in the seismological community. The IASPEI Seismic Format (ISF) was adopted as a standard format for exchanging seismic parameter data by the IASPEI Commission on Seismic Observation and Interpretation. The ISC as well as the NEIC and an increasing number of national data centers publish their catalogues in the ISF format, which also complies with the IMS1.0 format that was developed for the verification of the Comprehensive Nuclear Test Ban Treaty (CTBT). The ISF format description is available on the ISC-WEB site (<http://www.isc.ac.uk/standards/isf>).

A relatively new development is the format QuakeML. It was developed with special emphasis on real-time parameter exchange and in view of the need to frequently extend the format by data fields not contained in the standard itself. This is achieved by using XML as basis for QuakeML. More information on QuakeML can be found on the website <http://www.quakeml.org>

The products contain source and/or phase parameters. Products which include source parameters represent the seismicity within a given time period for a pre-defined area and above a reliable magnitude threshold. These limitations have to be taken into account, in order to provide a high quality product which claims to be of a high degree of completeness and accuracy.

Comprehensive products based on networks of stations distributed world-wide are published by the World Data Center (WDC) for Seismology (operated by NEIC, Denver, Colorado, USA) (<http://neic.usgs.gov>), the International Seismological Centre (ISC) (Newbury, England) (<http://www.isc.ac.uk>), and the International Data Centre of the Comprehensive Nuclear-Test-Ban Treaty Organisation (Vienna, Austria) (<http://www.ctbto.org>). The precision of these products with respect to epicenter location is  $\Delta D < 1^\circ$ .

In general, the products of national data centers and observatories provide data for events within an area that is well covered by the station network used for the data analysis. How complete these products are depends on the spacing between the stations, which also has a

major influence on the magnitude threshold. An example of such products is given by the German local bulletin of the Federal Institute for Geosciences and Natural Resources (BGR) at the following internet address: <http://www.bgr.bund.de/erdbebenkatalog-deutschland>. The precision of this product is  $\Delta D < 0.1^\circ$ .

Publication of teleseismic epicenter data from a regional network is useful only if the precision of the data is known or reliable calibration values for the correction of systematic location errors are available. Such a calibration for the GRF array/GRSN (see Section 8.7.5 and Fig. 8.17 in Chapter 8) is used by the BGR for determinations of epicenters world-wide in its teleseismic bulletin. The precision in the distance range  $D = 13^\circ\text{--}100^\circ$  is  $\Delta D < 3^\circ$  (see [http://www.bgr.bund.de/DE/Themen/Erdbeben-Gefahrungsanalysen/Seismologie/Seismologie/Erdbebenauswertung/Erdbebenkataloge/Teleseism\\_Bulletins/teles\\_bulletins\\_node.html](http://www.bgr.bund.de/DE/Themen/Erdbeben-Gefahrungsanalysen/Seismologie/Seismologie/Erdbebenauswertung/Erdbebenkataloge/Teleseism_Bulletins/teles_bulletins_node.html)).

However, if only phase parameters are available, it is also important for these to be reported to the international data centers, because these values are indispensable to improve the accuracy and comprehensiveness of their products. The ISC, for example, compiles a data catalogue based on reported phase parameter values received from a number of observatories and data centers world-wide (<http://www.isc.ac.uk/doc/analysis/2007p01/datacol.html>).

The information provided by a product also depends on how long after the event the product is to be published. For example:

## 2 Fast determination of epicenters of strong earthquakes

Information is provided for a single event immediately after it is detected and recognized as a strong earthquake or an earthquake which could cause substantial damage. The parameter values are obtained by automatic processing or manual analysis. They are published within minutes or hours after the event and are distributed mainly by e-mail or made available on the WWW. The NEIC publishes a near-real-time earthquake bulletin with about 20 recent earthquakes, which is updated every 5 minutes (<ftp://hazards.cr.usgs.gov/cnss/quake>). More detailed information is provided for the latest earthquakes in the world on the website [http://earthquake.usgs.gov/earthquakes/recenteqsww/Quakes/quakes\\_all.php](http://earthquake.usgs.gov/earthquakes/recenteqsww/Quakes/quakes_all.php). This website contains information for earthquakes of the last 7 days. A global, near-real-time earthquake bulletin is also produced by the GFZ Potsdam via the website <http://geofon.gfz-potsdam.de/eqinfo> where automatically produced earthquake information is published within minutes for significant events.

For local and/or regional purposes in Central Europe, fast epicenter determinations are also provided by the European Mediterranean Seismological Centre (EMSC) (<http://www.emsc-csem.org/Earthquake/index.php>). Epicenter determinations, which are received from national data centers, are automatically associated to the corresponding earthquake and published on the website for latest data contributions (<http://www.emsc-csem.org/Earthquake/seismologist.php>).

## 3 Preliminary products

Information is provided for all routinely analyzed events at regular time intervals, typically daily, weekly or monthly. This information may be subject to modification if phase readings from additional stations or arrival times of later phases are identified at a later stage of the

analysis or new data is received from contributing observatories. NEIC publishes, for example, their preliminary products on a weekly and monthly basis (<ftp://hazards.cr.usgs.gov/weekly> and <ftp://hazards.cr.usgs.gov/edr> , respectively). The BGR produces a preliminary event list of local, regional and world-wide seismic events with a time delay of 1 to 3 days. It is published on the BGR-website ([http://www.bgr.bund.de/DE/Themen/Erdbeben-Gefahrungsanalysen/Seismologie/Seismologie/Erdbebenauswertung/Detaillierte\\_Auswertung/Daten\\_GRS\\_GRF/grf\\_grsn\\_node.html](http://www.bgr.bund.de/DE/Themen/Erdbeben-Gefahrungsanalysen/Seismologie/Seismologie/Erdbebenauswertung/Detaillierte_Auswertung/Daten_GRS_GRF/grf_grsn_node.html)). Revised German products are the monthly distributed German local bulletin and the regional and teleseismic bulletin as described in section 1. All German products are based on the GERESS and GRF arrays, GRSN, and GEOFON networks. Additionally, seismic stations of neighboring countries, which provide online data access, are used for a precise determination of earthquakes in the border areas of the German station network. The results of local seismological services and observatories with their dense local station networks are also considered, in order to provide the German local bulletin with the best possible earthquake localizations.

## 4 Final products

The most complete and precise data on seismic events is published when all of the available data has been analysed. These products may be published up to several months after the events. ISC, for example, distributes their final products (<http://www.isc.ac.uk/doc/products/index.html>) about two years after the earthquakes occurred. The final ISC bulletin can be downloaded from the ISC website (<ftp://ftp.isc.ac.uk/pub/isf>) or can be requested at the ISC on compact disc. This bulletin comprises the most comprehensive information on global earthquakes including the final results of various national data centers and forms the base for scientific studies at universities and research facilities.

National as well as international data centers make their earthquake catalogues and bulletins available to the public on their WEB sites. In most cases it is also possible to search online for earthquake information in the data bases of the data centers. Requests can be individually configured for selected spatio-temporal criteria. This service is, for example, provided at the ISC website <http://www.isc.ac.uk/search/index.html>.

## 1 Introduction

Presented are 10 movies with animations of seismic ray propagation and the formation of seismic recordings in the distance range from  $0.1^\circ$  to  $167^\circ$ . Below we comment on each of these movies, which complement record sections presented in the Chapters 2 and 11 of this Manual. The animations can be opened by right mouse click on the file name **printed in bold blue letters** and then follow the instructions given below in section 2. The animation files can also be downloaded via the summary listing *Download Programs & Files* (see Overview on the NMSOP-2 cover page).

The development of such movies began at the University of Leipzig more than 20 years ago. Dr. Bernd Tittel, now retired from the University's Geophysical Observatory Collm, was an expert in identifying late and very late core phases. Therefore, the idea was born to produce an animation of the propagation of the seismic rays for such very late phases through a simple standard 1-D Earth model. The related seismic recordings of station Collm (CLL) were later added as standing pictures at the end of the movie. More than a decade ago one of us (S. Wendt) revived these earlier efforts by extending these animations to crustal, mantle and core phases in the local, regional and teleseismic distance range and by "writing" the sequence of records at several stations of local or regional networks as soon as the respective seismic phase rays arrive at these stations.

All ray paths and travel-time curves were calculated with the program TauP of H. P. Crotwell (1998) on the basis of the IASP91 Earth model (Kennett and Engdahl, 1991).

## 2 Software requirements and handling

The animations run on a Windows-PC with QuickTime Player 4 to 7. Quick Time Player can be downloaded from [www.apple.com](http://www.apple.com). After its installation, activate the event record file you wish to see in *Download Programs & Files*. Move with the cursor in front of the bold blue file name you wish to open. A right-mouse click opens a window which offers also the choices "copy hyperlink" and "open hyperlink". When you confirm with a left mouse click "open hyperlink" then - after a while - the cover page of the respective movie file appears in a frame. Start the movie by pressing the start-button  in the middle of the lower frame ridge. If this button is not visible then you have to reduce the frame size in the Quick Time Player menu line which appears above the movie cover frame. Click "Display Size" in order to adopt the movie frame to the size of your screen and then start the movie. The moving marker above

the lower command line will start running and the movie will show up. If you wish to hold-on the movie or control its speed at will then just catch the moving marker with your cursor and move it as you wish.

If lines, letters and numbers in the movie appear broken or blurred, the screen resolution has to be increased before starting QuickTime. Click “Start” in the desktop area, then “Settings”, and then “Display” on the appearing “Control Panel”. When “Display Properties” appears click “Settings” and there you may change the pixel number in the desktop area. Usually, a resolution of 1280x1024 pixels should be sufficient to resolve all details. Then return to the desk top, go back to *Download Programs & Files* and start the movie file again or select another such demonstration.

Yet, sometimes a much easier way works even when the film is already running. Go to “Display Size” and change there from “adapt to screen size” to “normal size”.

### 3 General structure and contents of the movies

Each movie file shows first a cover page in the start-frame, which gives the data, origin time, source co-ordinates and name of the source region of the earthquake. After starting the movie you will see, for all teleseismic earthquakes, the propagation of seismic rays of different phases, coded in different color, through a simplified cross section of the Earth. Shown are only those rays which will reach stations of the German Regional Seismic Network (GRSN). As soon as the different rays arrive at these stations, the onsets and associated waveforms will be “written” according to the original seismograms recorded at these stations from the considered earthquake. The response filters applied to the original velocity broadband records are given together with the record component in the record frames. The station codes and the epicentral distances to the stations are written on the ordinates and the travel times are marked on the abscissas of the record section frames. For all depicted phases, the theoretical travel-time curves according to the IASP91 Earth and travel-time model are also plotted in the respective phase color into the record frames.

Exceptions are the two local earthquake recordings (Files 1 and 2). Here the propagation of the Pg and Sg wavefronts and the formation of the related records at stations of the GRSN in different azimuths from the source are either shown in conjunction with the formation of the local travel-time curve (File 1) or on separate map projections.

### 4 Movie files and peculiarities of the recordings shown

Below the following information is given for each animation:

- file name;
- geographical region of epicenter;
- source parameters date, origin time OT, co-ordinates, source depth h;
- magnitude and data center which has provided these source data;
- the size of each animation file in megabyte (MB);
- the interval of epicentral distances D of the recording stations shown;
- remarks about the depicted seismic phases and recording frames;

- complementary remarks about the peculiarities of the records shown and the lessons learned from this demonstration.

For the definition of seismic phase names and complementary ray diagrams see IS 2.1. The original velocity broadband records have been filtered according to the response characteristics of standard seismographs, e.g., of type Kirnos SKD, SRO-LP, WWSSN-SP and WWSSN-LP. Their response curves are shown in Chapter 11, section 11.3.2 together with complementary record examples.

Note, that in the following the file names are printed in bold black, since they are not hyperlinked with IS 11.3.

**File 1: [wendt\\_vogtland1\\_qt](#)**

NW-Bohemia, Czech Republic, Novy Kostel

17.09.2000 OT=15:14:33.5 50.22N 12.47E h=10km Ml=3.1 (SZGRF)

23.0 MB

D=10–130km

Pg and Sg

**Left:** propagating wave fronts of Pg (blue) and Sg (red); **right:** records of some stations of the GRSN. Traces are sorted according to distance. At the moment of wave-front arrival at a station the onset and related waveform of this arrival is written in the record of the seismic station.

Note that the depicted travel-time curves for an average 1-D local crustal model match well with the onsets at the stations WERN, MOX and CLL but the onsets recorded at the stations GFRO and WET are about 2 to 4 s later than the onset times expected according to this model. This illustrates the need for improved local travel-time curves which may also be azimuth-dependent.

**File 2: [wendt\\_vogtland2\\_qt](#)**

Phases: Pg and Sg

**Left:** developing records at several GRSN-stations; **right:** propagating wave fronts of Pg (blue) and Sg (red).

When a wave front arrives at a station the respective onset and original waveform recorded at this station is written in the seismogram. The amplitude ratio Pg/Sg strongly varies with azimuth due to the different source radiation pattern for P and S waves with respect to the station azimuth (see Figs. 3.25 and 3.26).

Phases: Pn, (Pb?), Pg, Sn, Sb and Sg

Presented are the Z-component (above) and EW-component records (below) of WWSSN-SP filtered records of 8 stations of the German Regional Seismic Network (GRSN) (see diagram upper right) and a schematic crustal cross section (lower right) with the assumed ray-paths of the standard crustal phases Pg, Pb, Pn, Sg, Sb, and Sn. The following should be noted:

- 1.) Up to about 780km distance Pg is here the dominant phase onset in the early parts of the Z-component records;
- 2.) Yet, at the most distant station RGN Pn amplitudes are clearly larger than that of Pg which fall already in the signal-generate noise level;
- 3.) Pb, the critically refracted P wave from the mid-crustal Conrad discontinuity is not recognizable clearly in any record with the exception of the station RGN Z-component record, where it may be associated with slightly earlier than predicted arrival of a wave group with increased amplitude but no sharp onset;
- 4.) The P-wave onsets in the horizontal component records are generally smaller than in the Z component.
- 5.) Sg is the onset of the most prominent wave group with the largest amplitudes in the whole event record train;
- 6.) Sn is a clear earlier shear-wave arrival prior to Sg only in the horizontal component records and there also Sb has occasionally recognizably increased amplitudes, in this case at records of stations GRFO and CLL even with distinct onsets.

However, in the majority of earthquake records Pb and Sb are not well developed with clear onsets and significant SNR above the signal-generated noise between Pn and Sg.

Phases: P, pP, sP, PcP, PP, pPP, PPP, sPP, ScP

Strong phases P, sP and sPP on KIRNOS displacement BB Z-component records (top traces) of a deep Hindukush earthquake, whereas the reflections at the core-mantle boundary PcP and ScP are more clear in WWSSN-SP-filtered traces (bottom traces). The travel-time curves of PcP and PP intersect near 43° epicentral distance. This overlap distance is depth-dependent. Also note the simple impulsive P-wave onset from this deep source as well as the different amplitudes of the depths phases pP and pPP on the one hand and the much stronger depth phases sP and sPP on the other hand. This is due to the different P- and S-wave radiation pattern in the direction of the short up-going rays p and s, respectively (see Fig. 2.43). Stations situated in another azimuth from the same source may observe a different amplitude ratio of these depth phases.

Phases: P, PKKPbc, PKPPKPdf (P'P'df), PKPPKPPKPbc (3P'bc)

Shown are four short record windows, each one minute long, for P and pP as well as the multiple core phases PKKPbc, PKPPKPdf, and PKPPKPPKPbc with their respective depth phases. These late and very late core phases have travel-times of about 30, 38, and 59 min, respectively. Despite their long travel paths through the Earth, these late core phases still have an astonishingly good signal-to-noise ratio at most stations. They may easily be misinterpreted at individual stations as P-wave onsets from other independent events. Note the negative slowness of the phases PKKP and P'P'.

D=122°-126°

Phases: Pdiff, PKPpdf, PP, PPP, PS, PPS, SS, SSS, LQ, LR, 4PKPbc

The rarely observed phase 4PKPbc with a travel time of about 79 min is recorded with good SNR in the WWSSN-SP filtered traces (sampling rate of 20Hz). The projection of its path on the surface is  $(2 \times 360 - 124) \text{ deg} = 596 \text{ deg}$ . The long-period diffracted P-wave arrival Pdif (old name Pdiff) is well developed and arrives about 3.5 min ahead of PKPpdf in the SRO-LP filtered Z-component record (see record window in the lower left corner; sampling rate 1 Hz). The SRO-LP filtered Z-component (top left window) and T-component records (middle left window) show several mantle phases, a sharp onset of Love waves (LQ) in T and the onset of the Rayleigh wave LR in Z. The latter shows clear normal dispersion with rather long-period

waves ( $T \approx 1$  min) and large amplitudes at the beginning whereas shorter periods have much smaller amplitudes due to the intermediate source depth of this earthquake.

52.0 MB

D=160°-167°

Phases: PKP<sub>df</sub>, PKP<sub>ab</sub>, PP, PP2, PcPPKP, PPP2, SS, SSSS

The SRO-LP-filtered seismograms of this very distant event show remarkably strong PP2 and PPP2 onsets, which arrived at the stations from the opposite backazimuth over the long ray paths ( $360^\circ - D$ ). On the inserted map of Central Europe, which also shows the position of the stations of the GRSN, the passing of these wave fronts can be watched: The phases PKP, PP, PPP, SS and SSSS approach from the NE whereas the phases PcPPKP, PP2 and PPP2 approach from the SW. Also note that the wave fronts of the first arriving waves with rather small (steep) incidence angles have a very high apparent horizontal speed of wave propagation whereas the wave fronts of the later phases with large (shallow) incidence angles travel much slower through the network of seismic stations. Also note the well developed and very long surface-wave train from this shallow (crustal) earthquake. The surface waves arrive for this very distant earthquake more than one hour after the PKP first arrival.

## 1 Introduction

Modern digital acquisition systems (broadband sensors, timing with GPS or DCF-systems, sampling rates  $\geq 80$  Hz) and the use of modern analyzing software allow arrival-time determination of seismic signals with a precision of up to a few tenth of milliseconds. To benefit from this advancement in travel-time based methods like earthquake location and seismic tomography, consistent arrival time determination and error assessment (including uncertainty estimates of timing and phase interpretation) is crucial. Uncertainties of the arrival-time determination have to be provided in order to weight the data properly in the inversion procedure, i.e. arrival-time picks of high quality contribute more to the solution than those of low quality. The impact of such consistently picked and weighted data on tomographic models has recently been shown by several studies (e.g. Di Stefano et al. 2006, Diehl et al. 2009, Husen et al. 2009).

Although seismic arrival times represent the fundamental data of many seismological applications, the description of consistent phase picking receives only little attention. Simon (1981) and Kulháněk (1990 and 2002) provide a general overview about seismogram

interpretation from local to teleseismic scales. They focus mainly on basic descriptions of phases observable in common seismograms. The assessment of timing uncertainty and phase interpretation, however, is barely discussed. The fundamentals of digital signal processing and their influence on onset properties are described, e.g., in Seidl and Stammer (1984), Scherbaum (2001), and Scherbaum (2002). Among the few recent guidelines, the first edition of the *New Manual of Seismological Observatory Practice* (NMSOP) provides in Chapter 11 (Bormann et al., 2002) already an introduction to basic picking principles for local, regional and teleseismic seismograms, proposing the quantification of the onset-time reliability, yet a detailed description for consistent quality assessment is missing, similar to the discussion in Scherbaum (2001).

This tutorial is intended to provide a more detailed description on seismic phase picking. Basic principles (including a consistent quality assessment for timing uncertainty and phase interpretation) and common pitfalls of manual picking are described in section 2. In section 3, we present a practical procedure for consistent hand picking. The proposed method is especially intended for picking a reference data set for testing and calibrating of automatic picking algorithms, as described in Chapter 16 of NMSOP-2. The tutorial is focused on crustal and upper mantle phases of local and regional seismic events, recorded at epicentral distances from a few 10 km to several 100 km. But the outlined principles apply likewise to teleseismic records, however, then for different time and frequency resolution and recording bandwidth.

## 2 Routine hand picking

Especially for local and regional earthquake data, phase picking often becomes inconsistent and ambiguous due to rather complex waveform patterns and the close arrival of different phase types within a short time period of the same coda. In general, the shape of a seismic wavelet is affected by the source time function, the radiation pattern, dispersion, attenuation, scattering, interference with other phases, the signal-to-noise ratio (SNR) at the recording site, and the response characteristic of the recording system. The superposition of these components may lead to highly complex waveforms in case of high-frequency local and regional recordings. Moreover, the picking of later phases such as PmP or S-waves becomes even more difficult, since they interfere with the coda of earlier phases. Since the target accuracy of such arrivals is usually within few hundred milliseconds, errors like phase misinterpretations denote blunders and may significantly bias hypocenter locations and velocity models derived from onset-time observations. Furthermore, regional studies usually require the compilation of data from several networks. In such a case, merging routinely measured phase data will add even more inconsistency.

The possible sources for inconsistent hand picking described in the following sections refer mainly to P-wave picking. However, the basic principles of picking and error assessment of phases are also valid for S-wave picking. In addition, section 2.6 includes problems specific to S-wave picking.

In general, a seismic phase is defined by two visual observations:

1. Change primarily in amplitude:

The amplitude exceeds the background noise (for a certain amount of time). This can also be denoted as amplitude based signal-to-noise ratio (*ASNR*). We may define a phase, if its amplitude exceeds the background noise at least by a factor of 1.5 (*ASNR*

$\geq 1.5$ ). Figure 1 represents a typical example for a phase arrival defined by a change of the *ASNR*.

2. Change primarily in frequency:

A change of the dominant frequency indicates the arrival of a seismic phase. We can refer to this observation as frequency based signal-to-noise ratio (*FSNR*). Unlike the *ASNR*, it is often much more difficult to quantify visually. Moreover, the dominant frequency of noise and signal can sometimes be very similar. But especially for broad time windows, the *FSNR* can help to determine the approximate position of a phase. Figure 2 represents a typical example for a phase arrival defined by a change of the *FSNR*.

Once a phase is recognised based on *ASNR* or on *FSNR* or - most likely - a combination of both, we have to determine the precise wavelet onset ('arrival time'). However, its position is usually not completely independent from the associated overall observation uncertainty. Finally, we have to identify the phase type and to do so, we have to answer questions like: May we assign the ray path to the phase (Pg, Pn, PmP) with certainty or is the station near a triplication point (see Chapter 2, Figs. 2.29 and 2.40)? Are we sure that it is the first arrival or is it possible, that an earlier phase is hidden in the noise? In addition, the visual examination of *ASNR* and *FSNR* can be rather subjective and strongly depends on the width of the used time window and also on amplitude scaling. Finally, filtering can affect *ASNR* and *FSNR* significantly. In the following sections, we will give examples for these problems and suggest possible solutions in order to minimize inconsistencies during the picking process. Once identified, it should be possible to minimize their contribution by defining certain rules and procedures, which finally add up to a consistent picking workflow and consistent uncertainty assessment for each observation.

## 2.1 Phase Picking Part I: Phase timing and its error assessment

The basic quantities associated with a picked phase are usually the absolute arrival time and the corresponding observation error. However, it is difficult or even impossible to give a general definition of a seismic onset, which could be used for the actual measurement of first arrival time from a sampled band-limited signal in the presence of noise (Seidl and Stammer 1984). Therefore, the visual determination of absolute arrival times often implies a high degree of subjectivity and inconsistency. Consequently, a physical consistent formulation can only be achieved by a probabilistic point of view. Such an approach directly relates the measured arrival time with the corresponding observation error. Considering the onset of a seismic phase as probabilistic function  $P_a(t)$ , the arrival time is expressed as the "most likely" time  $t_A$ , with  $P_a(t_A) = \text{Max}(P_a)$ . On the other hand, the 'earliest' possible time for the phase onset is defined as  $t_E$ , where the likelihood for onset is approaching zero. Thus  $P_a(t_E) \geq 0$ . Similarly, the 'latest' possible time for the phase onset  $t_L$ , is defined as  $P_a(t_L) \geq 0$ .

Figure 1 illustrates the proposed concept for a typical *ASNR*-case in further detail. Although the onset of the phase is rather impulsive and exhibits an almost ideal SNR, it is difficult to determine an arrival time consistent with picks of waveforms from the same seismic source recorded at other stations. The thick grey band between position '1' and '2' defines the time window that for certain includes the onset of the wavelet. The band outlined by two broken lines denotes the possible threshold of the noise amplitude. In practice, we first determine the position of  $t_L$  and  $t_E$ . For a consistent determination of  $t_L$  and  $t_E$ , we have to setup a common

procedure. Since the amplitude exceeds the threshold several times at position ‘2’, the end of the grey band is certainly too late to be picked as  $t_L$ . Therefore, we define the intercept between signal amplitude and the a priori noise threshold (here: 1.5 times the largest noise amplitude in the noise-measurement time window) as  $t_L$ . Usually, the consistent determination of  $t_E$  is more difficult. In Figure 2 we fit a tangent (dashed line ‘a’) to the smoothed slope of the onset. If we shift the tangent from  $t_L$  towards earlier times, the slope decreases. The earliest possible time  $t_E$  corresponds with the first zero slope from  $t_L$  towards earlier time. Therefore, the start of the grey band (position ‘1’) is certainly too early and on the other hand,  $t_A$  would be too late to be picked as  $t_E$ . To ensure  $t_E$  includes the zero slope time in the presence of larger background noise, we could shift it to earlier arrival by approximately half a wavelength of the dominant noise. Subsequently, we pick the arrival of the phase at the most likely position  $t_A$ , within the error interval of  $t_E$  and  $t_L$  (e.g. on the seismogram’s leading edge). For the special case of an ideal delta-pulse,  $t_E$  and  $t_L$  would coincide with  $t_A$ .

**Figure 1** Probabilistic phase picking approach based on change of *ASNR*: the ‘earliest’ possible pick corresponds to  $t_E$ , the ‘latest’ possible pick corresponds to  $t_L$ . The most likely arrival time  $t_A$  is located within this interval. Primarily amplitude is used for determination of  $t_E$  and  $t_L$ . Copy of Fig. 2 in Diehl et al. (2009, p. 544) with © granted by the Geophysical Journal International.

Figure 2 illustrates a possible concept for the *FSNR*-case. Again, the thick grey band between position ‘1’ and ‘2’ defines the time window that for certain includes the onset of the wavelet and the band outlined by two broken lines denotes the possible threshold of the noise amplitude. The change in frequency is obvious for arrival times greater then position ‘b’. Therefore, we define  $t_L$  a quarter signal wavelength ( $\lambda/4$ ) after position ‘b’. For arrival times earlier than position ‘a’, the signal frequency, which dominates the grey-banded wavelet after position b, is certainly no longer recognizable. Therefore, we pick  $t_E$  half a signal wavelength ( $\lambda/2$ ) before position ‘a’.

The consistent determination of  $t_A$  in the ASNR as well as in the FSNR case can be difficult and might include some degree of subjectivity in practice. Although  $t_A$  in Figure 1 and 2 seems to be located halfway between  $t_E$  and  $t_L$ , a symmetrical distribution is not always appropriate and in some cases, a highly asymmetrical distribution is required (especially for broadband records). There is no universal definition for determination of  $t_A$ , but its position usually coincides with a prominent kink or discontinuity in the waveform, separating the noise from the signal. The position of  $t_E$  should include all possible earlier onsets of the picked phase. In that sense the utmost precision of  $t_A$  is less crucial as long as it is included in an appropriate uncertainty interval.

**Figure 2** Probabilistic phase picking approach based on change of  $FSNR$ : the ‘earliest’ possible pick corresponds to  $t_E$ , the ‘latest’ possible pick corresponds to  $t_L$ . The most likely arrival time  $t_A$  is located within this interval. Primarily frequency is used for determination of  $t_E$  and  $t_L$ .

Usually, the observation error is related with a discrete weighting or quality class (e.g. 0-5). However, these classes are often traditionally defined only through qualitative attributes, like waveform shape (impulsive or emergent). Such classification is not longer sufficient for a consistent error assessment. Instead, a quantitative weighting scheme has to be defined, which assigns the weighting class depending only on the measured time error interval  $t_L - t_E$ . In addition, the measurement of  $t_L$ ,  $t_E$ , and  $t_A$  allows us to adjust the weighting class definition even after the picking process. Finally, the availability of uncertainty intervals offers the possibility to assess the performance of automatic picking algorithms in a quantitative sense. Phase picks of automatic algorithms are expected to fall within uncertainty intervals of the corresponding manual picks. For more details on test and calibration of automatic algorithms see Chapter 16.

## 2.2 Phase Picking Part II: Phase identification and its error assessment

Although phase misinterpretation can result in significantly large errors, phase identification is typically not supplied with any observation error or uncertainty attribute at all (unlike arrival time of a phase). As demonstrated by synthetic travel time curves in Figure 3, the first arrival of the local or regional P-wave prior to its related coda is usually either Pg (direct wave as illustrated in the inset of Fig. 3) or Pn (Moho-refracted wave). Whether Pg or Pn is the first arriving wave depends on epicentral distance  $\Delta$ , crustal thickness  $z_M$ , and focal depth  $z_F$ . As a rule of thumb, Pn from a surface focus takes over Pg at  $\Delta \approx 5 z_M$ , for deeper sources, however, at shorter distances. Also Moho tilt and the direction of observation with respect to the direction of Moho dip influence both the slope of the Pn travel-time curve and the “take-over” distance (for both effects see Chapter 2, Fig. 2.40).

**Figure 3** Reflectivity seismograms (vertical components) and synthetic travel time curves (solid and dashed lines) for main phases observed in local and regional earthquakes (one layer over half space). Focal depth is set to 13 km and time axis is reduced by 5.8 km/s. Phase identification is expected to be difficult in the distance range of phase triplication. The position and width of this zone mainly depends on focal depth and Moho topography.

Moreover, the discrimination between Pg and Pn can become rather difficult in the distance range of phase triplication (see Fig. 3 as well as Figs. 2.28b, 2.29 and 2.40 with related texts in Chapter 2). The Moho-reflected PmP phase always arrives after Pg and Pn, although its amplitude can become the dominant phase in the coda. The synthetic reflectivity seismograms (Fuchs and Müller, 1971) in Figure 3 illustrate the theoretically expected amplitude ratios between Pg, Pn, and PmP for a simplified crustal model using a moment tensor as a source.

According to it, especially for large epicentral distances, Pn can be expected to be masked in the presence of noise and Pg or PmP then likely to be misinterpreted as the first arrival.

However, Figure 4 presents a velocity-reduced real record section and the related travel-time curves for Pg, Pn and Pm from a local earthquake near Walenstadt, Switzerland with a focal depth of 13 km. It looks very different from the synthetics in Figure 3, calculated for a source at the same depth in the same simplified crustal model. From this it is obvious that, based on synthetic waveform characteristics alone, phase interpretation is rather difficult. Real records of seismic waves that have been radiated by extended seismic sources and travelled through complex media, resulting in multi-pathing and long codas, may look very different. In Figure 4 this holds especially for records at some stations in the distance range of phase triplication (e.g., station SPAK and SIERE). Also the amplitude ratio between Pg and Pn exhibits strong variations between some stations (e.g., EMV and HEI), probably due to 3D Moho topography and/or the influence of the source radiation pattern, which effects the Pn/Pg amplitude ratio because of the rather different take-off angles of these two waves from the source. Whereas in the case of EMV Pn is likely to be missed and Pg be picked as first arrival phase Pn is an unexpectedly large and sharp onset at station HEI. Moreover, for distances above some 400 km there is a tendency of Pn (which then becomes more and more a diving phase in the uppermost mantle, usually not modelled by any synthetics) to have larger amplitudes than Pg, which is more strongly attenuated and/or scattered in the more complex upper crust. This is illustrated by many record examples in DS 11.1. Similarly, as obvious from Figure 4, the determination of the phase type from generalized waveform features alone can also be rather ambiguous in the range of the crossover distance between Pg and Pn.

Since most applications like hypocenter localisation and travel-time tomography are (still) based on first arrivals only, an assessment for phase identification should avail of some guidance to avoid inconsistencies. The relevance of correct phase interpretation becomes even more evident for S-wave picking (see section 2.6). For use in routine first-arrival studies and subsequent special tomographic studies at local to regional distances, we therefore propose to identify crustal phases according to the rough waveform characteristics outlined below and to decide about their suitability for first arrival studies according to the assessment scheme presented in Table 1.

**Table 1** Suitability assessment scheme of crustal phases for routine first arrival studies.

| Phase label | Phase is...                               | Phase used for routine 1 <sup>st</sup> arrival studies |
|-------------|-------------------------------------------|--------------------------------------------------------|
| Pg, Sg      | Direct (crustal)                          | Yes (if first arrival)                                 |
| Pn, Sn      | Moho-refracted                            | Yes (if first arrival)                                 |
| PmP, SmS    | Moho-reflected                            | No                                                     |
| P1, S1      | Unknown type, but certainly first arrival | Yes                                                    |
| P2, S2      | Unknown type, second arrival              | No                                                     |
| P3, S3      | Unknown type, third arrival               | No                                                     |
| P, S        | Unknown type, uncertain if first arrival  | No                                                     |

- **Pg:** Impulsive high-frequency onset. At short distances, absorption is small and dispersion tends to sharpen the wavelet front (Seidl and Stammer 1984). Pg is first arrival close to epicenter.
- **Pn:** Usually with small amplitude at  $\Delta < 400$  km, impulse or emergent onset. The wavelet front may be smoothed for increasing distance since absorption becomes dominant (Seidl and Stammer 1984). Pn is first arrival for larger epicentral distance, usually followed several seconds later by stronger Pg and PmP phase, if Pg is not yet

strongly attenuated at distances  $\Delta < 400$  km. As a rule of thumb, Pn from a surface focus takes over Pg at  $\Delta \approx 5 z_M$ , for deeper sources, however, at shorter distances.

- **PmP**: Has the largest amplitude of all crustal P phases because of total reflection from the Moho at overcritical incidence angles. PmP is never first arrival but follows very closely Pg (with  $\delta t < 2$  s) after Pn has taken over as first arrival.

**Figure 4a)** Velocity-reduced record section of a local earthquake near Walenstadt, Switzerland. Amplitudes are normalised to maximum amplitude of each trace. Solid and dotted lines indicate synthetic travel-time curves for Pg, Pn, and PmP.

**b)** Velocity-reduced phase picks, crosschecked against synthetic travel-time curves derived from a simplified crustal model for the area under investigation (see text for discussion). Copy of Fig. 3 in Diehl et al. (2009, p. 545) with © granted by the Geophysical Journal International.

### 2.3 Phase Picking Part III: First-motion polarity and its error assessment

Information about first motion polarity is mainly needed for focal mechanism determination. Usually the polarity is denoted as ‘Up’ or ‘Down’. Figure 1 represents an example for certain polarity identification. On the other hand, it is impossible to determine any polarity for the example of Figure 2. However, besides these two obvious cases, it is sometimes necessary to use an intermediate quality class for the first motion polarity. Time ‘a’ and ‘b’ in Figure 5 represent two possible positions for arrival time picks. In this case, the polarity is depending on the location of the pick. If the pick is assigned to position ‘a’, the polarity would be ‘Up’. If position ‘b’ is used, the polarity has to be ‘Down’. In both cases, we are not sure about the actual polarity, therefore we have to introduce an intermediate quality classes ‘+’ or ‘-’. The error assessment scheme used here is summarized in Table 2.

**Figure 5** First-motion polarity and its error assessment: In this example the first-motion polarity is not independent from the pick position. If the pick is assigned to position ‘a’, the polarity would be ‘Up’. If position ‘b’ is used, the polarity has to be ‘Down’. In both cases, we are not sure about the actual polarity. Therefore we have to use the intermediate quality classes ‘+’ or ‘-’.

**Table 2** Error assessment used for first-motion polarity.

| Polarity label | Polarity is... | Weight                                |
|----------------|----------------|---------------------------------------|
| U/D            | Up/Down        | Polarity is identified with certainty |
| +/-            | Up/Down        | Polarity is identified but uncertain  |
| N              | None           | Polarity cannot be identified         |

### 2.4 Size of time window and amplitude scaling

The influence of time-window size and amplitude scaling on picking accuracy and phase identification as described e.g. by Douglas et al. (1997) is demonstrated in Figure 6a-d. In the uppermost example, the used time window is 5 s (Fig. 6a). The picked onset is labelled as  $P_a$ . For a narrower time window of 1.5 s, the onset at  $P_a$  seems a bit too late (Fig. 6b). Thus, we would pick the phase at position  $P_b$  in this window. The result is even more different, if the time window size remains the same, but the amplitude is multiplied by a factor of 5 (Fig. 6c) and 10 (Fig. 6d) respectively. An earlier phase is visible, which can be picked as  $P_c$  (Fig. 6d). But not only the absolute timing of the picked phase depends on window size and amplitude scaling, also the assigned uncertainty interval. The error interval might be smaller for the narrower time window and the magnified case.

**Figure 6** Different phase picking, caused by variable use of time window size (a, b) and scaling (c, d). See text for further discussion.

Considering the magnitude of the event, the small, ramp-like phase  $P_c$  in Figure 6 might be associated with the initiation of the fault rupture.  $P_c$  is obviously the first arriving phase, but it is arguable if it can be observed at stations with lower SNR (e.g., at larger epicentral distances). To obtain a consistent set of picks for the same earthquake it may be considered to pick the first prominent phase ( $P_b$  in Figure 6) instead. In contrast to the small precursory phase, the first prominent phase is expected to be observable at the majority of stations. Only precursors related to rupture complexities could be treated this way. Instead,  $P_c$  in Figure 6 might also be interpreted as the evolving Pn, taking over Pg as the first arriving phase. In this case,  $P_c$  has to be picked as the first arriving phase and cannot be ignored. Complexity of the source function usually scales with the rupture area. Therefore, small events ( $M < 4$ ) can be approximated as point sources in the far field and the shape of Pg is expected to be rather simple and impulsive. As mentioned earlier, an evolving Pn phase beyond the take-over distance between Pg and Pn can have the signature of a precursor signal. Similar effects are expected in subduction environments, where slab-phases are commonly observed. Such slab-

phases travel through the faster lithosphere of the subducting plate and manifest as precursors prior to the direct phase. Finally, it should be noted that interpretation of precursor signals requires the detailed knowledge of the complete instrument response as described in the following section. As demonstrated by Scherbaum (2001), precursor signals are often just artefacts of the instrument's anti-alias filter.

## 2.5 Aliasing and waveform filtering

From signal theory we know, that the correct digital representation of a continuous waveform depends on the sampling frequency. To avoid aliasing, a signal with frequency  $f$  has to be sampled with a sampling frequency  $\Delta f > 2f$ . Thus, the Nyquist frequency is defined as  $f_N = 1/(2\Delta t) = \Delta f/2$ . Any frequencies higher than  $f_N$  are aliased into lower ones. Therefore, we have to ensure that picking accuracy and phase identification will not be affected by sampling rates, which are rather small. As an example we consider a waveform sampled at  $\Delta f = 20$  Hz or  $\Delta t = 0.05$  s, which corresponds to a Nyquist frequency of  $f_N = 10$  Hz. Concerning the observation error of a phase pick, the uncertainty intervals can not be smaller than the sampling interval. Therefore, the minimum picking uncertainty is defined as  $\pm\Delta t$ . To avoid possible inconsistency due to significantly different sampling rates used at different stations, we suggest to use only data with  $\Delta f \geq 40$  Hz for local earthquake studies.

Aliasing occurs when the data are sampled, and once this occurs, the data cannot be 'unaligned'. Therefore, seismic data are usually filtered with an analogue anti-aliasing filter to remove frequencies above the Nyquist frequency before sampling. Furthermore, modern acquisition systems make use of oversampling and decimation techniques (Scherbaum, 2001; NMSOP Chapter 6). Such systems imply digital anti-alias filters, which often denote symmetrical or acausal impulse responses to avoid time shifting of the phases (zero-phase). As a consequence, the onset of very impulsive signals (also signal with frequency close to Nyquist frequency) may be obscured by 'acausal' precursory oscillations and their true onset becomes difficult, if not impossible, to determine. As an example for such precursors, Figure 7 shows the P-wave recording of a local earthquake near Davos, Switzerland (2006/10/24 13:08,  $M_l = 2.6$ ) at the nearby station DAVOX.

In principle, this effect can be minimized by an inverse filtering process, described e.g. in Scherbaum (2001). However, this nontrivial procedure requires knowledge of the original anti-alias filter coefficients. Especially for large and inhomogeneous data sets, compiling the correct information can be rather difficult or even impossible. An alternative way to deal with this problem is to apply a consistent error assessment to it, as it is described above. The significance strongly depends on the amplitude scaling as discussed in 2.4 and low-pass filtering or integration of the signal may also help to reduce the amplitudes of such precursors. Since these precursors are present only for very impulsive and/or high-frequent wavelets, they are expected to be limited to recordings close to the epicenter and/or with low sampling rates and large relative bandwidth.

**Figure 7** Precursors caused by acausal anti-alias filtering observed on the broadband registration of a local earthquake near Davos, Switzerland (2006/10/24 13:08,  $M_I = 2.6$ ). Sampling frequency is 120 Hz. The precursors become obvious for enlarged amplitude scale (lower trace).

Filters are usually applied to enhance the SNR in the presence of noise. However, filtering can significantly change the true shape of the arriving wavelet and may also result in time-dependent phase shifts within the signal group (so-called “transient response”). These effects are particularly pronounced in narrow-band records (see section 4.2 in Chapter 4, e.g., Fig. 4.18). Therefore, care has to be taken when applying filters in the picking process. First of all, it should be noted that the original seismic record itself is the output of a filter (transfer function of sensor and digitizer), which distorts the true ground motion input depending on its relative bandwidth. Only a record of infinite bandwidth could reproduce the ground motion undistorted. Commonly used band-pass or high-pass filters not only reduce the amplitude of the noise, but can also result in distortion and phase shift of the signal. The phase shift introduced by a filter depends on the instrument response, the filter response and the frequency content of the signal. The closer the signal’s dominant frequency is to the corner frequency  $f_c$  of the filter, the stronger the expected effect on the signal. Moreover, the steeper the flanks of the filter (higher order), the stronger are the expected effects on frequencies close to  $f_c$ .

Figure 8 demonstrates the effect resulting from the application of an arbitrary filter to a velocity proportional short period record. The corner frequency of the 2<sup>nd</sup> order high-pass filter ( $f = 1$  Hz) is close to the dominant frequency of the first part of the wave group. Application of a 2<sup>nd</sup> order high-pass increases the effective steepness of the velocity proportional pass-band to the 5<sup>th</sup> order. This leads to an increased distortion of signals close to corner frequency, even for  $f > f_c$  (see also Figures 7a and 7b in IS 5.2). As a result, the filter significantly affects the low-frequent part of the signal as demonstrated in Figure 8. Position

‘a’ and ‘b’ represent two possible arrival-time picks on the original and the high-pass filtered record. Time difference between the two positions could exceed 0.2 s, a value much larger than the uncertainty of each individual pick. Moreover, the filter process affects the first-motion polarity. A similar effect is demonstrated in Fig. 4.10 of Chapter 4.

In general, the use of filters has to be consistent for arrival-time picking. If broadband and short-period instruments are present in the same network, a common frequency band should be used to avoid inconsistencies between the two types of instrument responses. The application of a 2<sup>nd</sup> order high-pass with  $f_c = 1\text{ Hz}$  to a broadband record is appropriate to sufficiently simulate a short-period instrument response. Further practical guidelines for the use of filters are provided in section 3.1.

**Figure 8** Effect of 2<sup>nd</sup> order Butterworth high-pass filter (1 Hz) on a short-period waveform. Note the significant change in waveform between the original and the filtered trace. The earliest low-frequency onset is hardly observable on the filtered trace. Position ‘a’ and ‘b’ represent two possible arrival picks for each trace with a time difference that exceeds 0.2 s. See text for further details.

## 2.6 Additional comments for S-wave picking

Most of the previous findings apply likewise to S-wave picking, however, identification and picking of S-waves is usually more difficult, since its onset is often superposed by the P-wave coda. Furthermore, we have to consider S-wave splitting due to possible seismic anisotropy and the presence of Sp-converted precursors due to the presence of shallow strong velocity discontinuities.

### 2.6.1 Polarization of the wavefield

According to linear theory of wave propagation in homogeneous isotropic media P and S waves are fully independent solutions of the equation of motion results with linear particle motion. Figure 9 illustrates the particle motions of P and S waves in the horizontal (a) and vertical (b) planes of wave propagation. The particle motion of the P wave is parallel (or

longitudinal) to the direction of wave propagation vector  $\mathbf{k}$ . In contrast, the displacement field of the S wave is transverse to  $\mathbf{k}$  and can be subdivided into a vertical component (SV) and a horizontal component (SH). The vector  $\mathbf{k}$  can be described in the Cartesian ZNE-system of the seismometer (vertical, north-south, east-west) by two angles: the backazimuth ( $BAZ$ ) and the angle of incidence ( $i$ ). Both angles can be determined from polarization analysis of a three-component recording in a window around the P-wavelet. If station and epicenter coordinates are known,  $BAZ$  can also be derived from the orientation of the great-circle including station and epicenter. If focal depth and epicentral distance are known, we can also determine the theoretical angle of incidence in a given velocity model. However, in real inhomogeneous Earth the true arrival angles  $BAZ$  in the horizontal and  $i$  in the vertical plane depend on frequency and thus wave length (see Fig. 2.6 in Chapter 2 and Fig. 11.23 in Chapter 11).

**Figure 9** Particle motion for P and S wave along wave propagation direction a) in the horizontal plane and b) in the vertical plane.

Both angles can be used to rotate the ZNE coordinate system into a local ray-system. Within the ray system P, SH, SV components can be partly separated from each other. The horizontal rotation of ZNE by  $BAZ$  results in the ZRT-system as demonstrated in Figure 9a.

The T-component denotes the transverse component, i.e., perpendicular to the direction of wave propagation in the horizontal plane, R coincides with the radial component, i.e., in the horizontal direction of wave propagation. In the ideal case of a flat-layered isotropic medium, the T-component contains only SH energy. P- and SV-energy are still mixed on Z and R to a variable degree, depending on the incidence angle  $i$  and the source mechanism (see Chapter 3). An additional rotation of ZRT by the incidence angle  $i$  results in a decoupled ray-system LQT. The complete P-wave energy is then recorded on the L-component (longitudinal) and the Q-component contains the SV energy only. The T-component remains the same as in ZRT.

Since both P and SV are polarized in the vertical plane of propagation, SV-wave energy incident on a velocity discontinuity can partly be converted into a P wave during reflection at or transmission through such an interface (or vice versa P into SV). If such an interface is close to the surface and denotes a strong velocity contrast (e.g. basement-sediment interface), Sp precursors are generated, which then arrive shortly prior to the initial SV-wave. These Sp precursors may be misinterpreted as a too early onset of the S-wave. The use of a ray-system can be used to identify such precursors, as demonstrated in Figure 10. Sp precursors are not present on the T-component, since there is no coupling between SH and P. However, the ratio between radiated SH and SV energy strongly depends on the focal mechanism and its orientation in space and thus also on the observation azimuth.

To avoid the misinterpretation of Sp precursors as the true S-wave arrival we recommend the use of a ray system (ZRT or LQT) and pick the S wave preferable on the T-component. Furthermore, the use of a ray-system can be helpful for a better discrimination of S energy generated by the P coda and to identify phases like Sn as demonstrated in Figure 10. In addition, the application of a Wood-Anderson simulation filter (high-pass with  $f_c = 1$  Hz in combination with an integration from velocity to displacement) can be useful to enhance the S-wave onset. The final S-pick, however, should be crosschecked with its position on the velocity proportional record.

**Figure 10** Theoretical seismograms calculate by the reflectivity method of Fuchs and Müller (1971) for a simplified 1D crustal model (upper right inset) using the *refmet* code provided by T. Forbriger. The uppermost layer represents a sedimentary basin of reduced P- and S-wave velocities. The uppermost traces show vertical, radial and transverse component at a distance of 20 km. The Sp precursor phase is clearly visible on Z and R component. The lowermost traces correspond to a distance of 150 km. The amplitude of the first arriving Sn phase is rather weak compared to later arrivals (Sg, SmS) and only visible on the T component. All amplitudes are normalized by the calculated maximum record amplitude for the considered station.

Another form of S-wave “splitting” results from travelling through anisotropic Earth material. In such media part of the SV-wave energy is coupled with some time shift into the T component, producing instead of a linear SV motion a more or less elliptical S-wave motion in the R-T plane. The degree of ellipticity and the amount of time shift between the related S onsets in the R and T component depend on the degree of anisotropy of the medium through which the S wave is travelling. Furthermore, the time shift depends on the angle between the anisotropy axis and the incident angle of the S wave and therefore it depends also on the epicentral distance. This allows to determine the degree of (specifically horizontal) anisotropy and its orientation in space by restoring iteratively the linear motion of SV expected for isotropic media. This is illustrated, e.g., by Fig. 2.7 in Chapter 2 for teleseismic SKS waves. The time shift between the first S arrivals in R and T may range between several tenths of seconds and several seconds, depending on what type of S waves one analyzes at which frequencies and source distances and with focus on which parts of the Earth (e.g., crust, upper mantle or deeper). Also in this case it is helpful to analyse arrivals in the S-wave range and their polarization in a ZRT or LQT system in order to discriminate between onsets in different components due to wave conversion at a discontinuity or caused by true S-wave splitting due to travel through anisotropic Earth material.

### 3. Consistent hand picking procedure

The findings discussed in the previous sections will be combined to a standard procedure for consistent P- (and S-) phase picking in the following sections. This requires, first and foremost, that the picking is made on some standardized type of seismic record and that time window length and the amplitude scaling are chosen consistently. Therefore, we will discuss in detail these major sources for inconsistent picking.

#### 3.1 Consistent waveform filtering

As demonstrated in section 2.5, filtering may lead to inconsistent picking. Therefore, we suggest the following guidelines:

- The original seismic record itself is the output of a filter, which distorts the true ground motion input depending on its relative bandwidth. Only a record of infinite bandwidth could reproduce the ground motion undistorted (see Chapter 4).
- Since for local/regional applications emphasis is on high-frequency signals one should preferably use either directly original short-period (SP) records or filter BB records accordingly so that the lower corner frequency  $f_{cl}$  of the passband is about 1 Hz.
- Short-period (SP) channels (EH, SH):  
Typical SP sensors are electromagnetic seismographs of the geophone type with a seismometer eigenfrequency  $f_s \approx 1\text{ Hz}$  (or higher). They have a response proportional to ground motion velocity between  $f_s = f_{cl}$  (lower corner frequency) up to the corner frequency  $f_{cu}$  of the anti-aliasing filter. If  $f_{cu} = 10\text{ Hz}$ , respectively  $50\text{ Hz}$  (i.e., if the data are sampled with  $\Delta f \approx 40\text{ Hz}$ , respectively  $200\text{ Hz}$ ) then this corresponds to a velocity-proportional relative bandwidth (RBW) between some 3.5 to 5.5 octaves or 1 to 1.7 decades. Note that this is much less than for modern broadband seismographs,

which also have a velocity-proportional response but within the range  $f_{cl} \ll 1$  Hz (up to  $\approx 0.3$  mHz) and  $f_{cl} \approx 10$  to  $20$  Hz (with  $\Delta f \geq 40$  Hz), corresponding to an RBW between some 2 to 4 decades. Note, however, that the RBW of common bandpass-filtered SP seismographs used for teleseismic observations is only about 1 and 2 octaves (e.g., Fig. 4 in Granville et al., 2005) and should not be mistaken with the SP sensors considered here for local and regional travel-time studies.

- To avoid aliasing-effects, be sure that the upper corner frequency  $f_{cu}$  of the filter is well below Nyquist frequency, typically at  $\leq 1/4^{\text{th}}$  of the sampling rate  $\Delta f$  and with a steep roll-off for  $f > f_{cu}$ .
- Unfiltered SP sensors have already a limited bandwidth with a step  $3^{\text{rd}}$  order roll-off of the response for  $f < f_{cu}$  (see Fig. 5.3 in Chapter 5) which results in significant phase shift and distortion of the earliest parts of the waveform (for frequencies up to about 3-4 times  $f_{cl}$ ).
- Therefore, one should avoid further frequency filtering when ever possible. Apply a  $2^{\text{nd}}$  order 1 Hz high-pass filter only if necessary, e.g. in presence of low-frequency noise. This filter will not affect the velocity-proportional passband, yet be aware that it will steepen the roll-off for  $f < f_{cl}$  to  $5^{\text{th}}$  order, thus causing larger phase shifts and waveform distortions up to  $f \gg f_{cl}$ . Therefore, compare original waveform with filtered one before final picking. Also check, if the filter changes first motion polarity.
- Apply possible low-pass or band-pass filters only if necessary, e.g., in presence of high-frequency noise. Compare original SP waveform with filtered one before final picking.
- Broadband (BB) channels (HH, BH):  
Modern feedback-controlled BB seismographs are widely in use now. They have also velocity-proportional response for  $f > f_{cl}$  (see Fig. 11.27 in Chapter 11). If one applies a high-pass filter with corner frequency 1 Hz to such a wider broadband records with  $f_{cu} \ll 1$  Hz it will remove the long-period noise often present in BB recordings, and in addition, will simulate well the response of an original 1 Hz SP record of the geophone type. Thus, filtering BB records with a constant  $f_{cu} = 1$  Hz will minimize the inconsistency due to different types of BB sensors used in practice.
- S-wave identification and picking:  
Application of a Wood-Anderson simulation filter ( $f_{cl} = 1$  Hz in combination with an integration from velocity to displacement) can be useful to enhance the S-wave onset. In addition, component rotation to the RT-system can help to identify the S-wave on the T-component.

### 3.2 Consistent window size and amplitude scaling

A uniform procedure is required to minimize subjectivity in phase picking due to irregular choice of time window size and amplitude scaling as shown in Figure 6. On the other hand, it turns out to be very difficult to define universal rules, especially, if the method should be feasible for picking of large data sets. A consistent choice of time window and amplitude

scaling should satisfy two conditions: A fixed time window length and amplitude normalisation with respect to a reference scale.

As already mentioned, universal rules for these conditions are difficult to define. Concerning the time window length, the choice depends on the dominant frequency of the signal, but also on the  $ASNR$ . In the presence of strong noise or in the case of a weak and emergent signal, it is often better to use a broader time window to determine the change in frequency and follow the transition from the signal to the noise part. In addition, many picking tools normalise the amplitude to the maximum amplitude within the selected time window and therefore amplitude scaling depends also on the size and the position of the time window. A possible approach to minimize the inconsistency related to time window choice and amplitude scaling may consist of a mixture of iterative selection of window sizes and sliding them stepwise from the signal part towards the noise dominated part. For a further description, we apply this approach to the example shown in Figure 6. A priori, we define four possible time windows used for picking:

|                                                                      |      |                   |
|----------------------------------------------------------------------|------|-------------------|
| Length of <b>H</b> igh- <b>R</b> esolution <b>W</b> indow (HRW):     | 2 s  | $ASNR \geq 3$     |
| Length of <b>M</b> id- <b>R</b> esolution <b>W</b> indow (MRW):      | 5 s  | $2 \leq ASNR < 3$ |
| Length of <b>L</b> ow- <b>R</b> esolution <b>W</b> indow (LRW):      | 10 s | $ASNR < 2$        |
| Length of <b>V</b> ery-low- <b>R</b> esolution <b>W</b> indow (VRW): | 15 s |                   |

In the first step we choose a broad overview window, which includes the whole coda of P or even parts of the S-coda (Fig. 11a). ‘P-PRED’ denotes the theoretical arrival time predicted in a velocity model for a preliminary hypocenter. The predicted arrival time can be useful, but only as a rough guide and is not necessary. We pick the approximate position  $P_{approx}$  of the earliest arrival visible in this window. Based on  $P_{approx}$ , the maximum noise and signal+noise amplitude is estimated. To avoid parts of the signal in the noise window, we define a safety gap of  $\pm 0.5$  s around  $P_{approx}$ . We use a length of 3 s for the noise window and of 0.5 s for the signal+noise window. We define the noise threshold as  $\pm 1.5$  times the absolute noise amplitude within the noise window. In addition, we calculate  $ASNR$  from the absolute noise and signal+noise amplitudes. Depending on the resulting  $ASNR$ , we choose the appropriate window size as described above.

In Figure 11b  $ASNR$  is several times larger than 3, therefore we use the HRW-size for picking. Between Figure 11b and 11e, the time window is shifted stepwise towards earlier times. The maximum amplitude within each time window is used for amplitude scaling. As long as the upper and lower noise threshold (dashed horizontal lines) are close to each other, the time window can be shifted further to earlier times (i.e. enlarging the amplitude scale). Finally, in Figure 11e, the amplitude scaling allows an almost perfect discrimination between noise and signal. In this example, the suggested procedure prevents missing the small precursors. If we could not clearly distinguish between noise and signal with the actual window size, or if we are not sure whether it is definitely the first arrival (e.g., in the presence of strong noise), we repeat the sliding procedure with a larger time window (MRW or LRW). Subsequently, we apply the consistent error assessment as described in section 2.1 to determine  $t_L$ ,  $t_E$ , and  $t_A$ . The upper and lower noise thresholds (dashed horizontal lines) are used for the consistent determination of  $t_L$ .

**Figure 11** Sliding time window procedure used for consistent phase picking. See text for further details.

### 3.3 Consistent phase identification

Provided that a hypocenter can be calculated, the actual phase identification can be crosschecked against a simplified crustal model (similar to Figure 4b). Another helpful tool to minimize inconsistency due to phase misinterpretation can be the use of synthetic or predicted arrival times, especially for re-picking of seismograms. However, as the comparison of Figures 3 and 4 shows, the actual phases may look very different and also their onset times may significantly deviated from the synthetic ones. Therefore, one should never pick the onsets at the theoretically predicted arrival times and identify the phase on waveform synthetics, unless all the subsequently applied criteria for phase identification and picking, as described above, are sufficiently well fulfilled. Because our goal is not to confirm already existing, usually grossly simplified 1-D models but to substitute them by high-resolution 2- and/or 3-D models by picking well-established deviations of correctly identified real phase onsets from theoretically predicted ones.

If, however, a reasonably accurate local or regional velocity model is available and a preliminary hypocenter has been calculated on the basis of such a model, we can calculate synthetic first arrival times for each event-station pair, prior to the picking process. This provides three major advantages. First, they may guide the picker to the right phase (but as said above, with the reliability depending on model quality) and thus reduce phase misinterpretations. Second, the synthetics can also be used to arrange the seismograms according to their expected arrival times. Thus, one can start the picking at the closest station and does not waste too much time with likely low quality arrivals. In addition, the synthetics may give at least some rough guidance for recognizing and tracking possible, theoretically expected changes in waveforms from station to (neighbouring) station. Third, it represents a rough test for correct synchronization of the timing system. In case of obvious timing errors of a station, we would observe a large discrepancy between synthetic and actual waveform arrival.

### Acknowledgments

Seismograms were processed and displayed using the ‘SeismicHandler’ package (Stammler 1993) and additional figures were generated with the Generic Mapping Tool by Wessel and Smith (1995)

## 1 Introduction

The Seismogram Picking Error from Analyst Review (SPEAR) project was initiated in 2006 to determine the reliability and accuracy of picks made by analysts. The process of picking is defined as the timing, measuring and naming of seismic phases used to locate and classify seismic events. Prior to this study only one analyst-based study had been conducted (Freedman, 1966a). While the general practice and theory of picking has not changed significantly from 1966, the technology and tools used to analyze waveforms has improved, along with the resolution of digitized waveforms (Lomnitz, 2006). Additionally, the 1966 study was limited to a small subset of analysts that used paper records. To continue and modernize the study of analyst based picks, we implemented a two-part study by first looking at available catalogue data (Zeiler and Velasco, 2009) and then by creating a common data set for analysts to pick.

The initial looks at archived data provided a limited data set to further understand pick error. Zeiler and Velasco (2009) established a pick model for a single analyst and found that picks from different institutions could be biased. However, they could not establish a complete error model. To produce a more reliable error model, a more robust technique to test and study the effects of different analysts reviewing the same seismograms must be implemented. The current SPEAR effort is designed to provide a common data set for analysts from varying experience levels to pick. An updated model is generated with each new participant. The current approach is designed to focus on signal quality and analyst experience. While many studies have tried to estimate pick error (Freedman, 1966a, 1966b, 1967a, 1967b and 1968; Buland, 1976; Pavlis, 1986 and 1992; Billings et al.; 1994, Sipkin et al., 2000), our approach can uniquely remove pick errors from the travel-time modeling errors.

## 2 History of the study

Zeiler and Velasco (2009) studied catalogue data to test the reliability of a single analyst's picks and compare the repeated picks from different institutions reported in the catalogue of the International Seismology Centre (ISC). The single analyst picks were obtained from a local network operator, who reviewed or made each pick on local to near regional events. With over twenty years' experience picking the waveforms, the operator showed consistency within 0.10 seconds when working on waveforms with high signal-to-noise ratio (SNR > 10). Since, the signal quality is not documented in the ISC catalogue, Zeiler and Velasco (2009) were only able to show that there can be a bias based on institution or who is making the

picks. The initial study confirmed that the study of pick error could not fully be conducted on pre-existing data base information.

The current iteration of the SPEAR study relies on a common data set of varying types of waveforms for analysts to pick. The waveforms include the same event recorded at various distances, different types of sources, and synthetic pulses with varied SNR. A broader suite of seismograms would be ideal, but limiting the time constraint to pick the seismograms has been a primary goal of the experiment. Currently the data set can be picked in under an hour by most analysts. Since the project is an on going effort, **we encourage interested institutions or analysts to contact the authors** for any related question **and download the common data set and user guidelines** via the link *Download programs and files* from the NMSOP-2 front page.

The SPEAR study has collected picks during two main efforts (Table 1). In each effort the analysts have only picked phases they could identify. Then, after a minimum of six months, the analysts have re-picked the data to test their consistency of picking over time. The commitment to pick the data set twice is not required for the study, but is encouraged to help understand picking precision and its improvement with time and experience.

**Table 1** The growth of the SPEAR project from the inception to the last review of all picks that have been submitted by 2011.

| Year | No. of Analysts | No. of institutions | No. of waveforms | No. of picks |
|------|-----------------|---------------------|------------------|--------------|
| 2006 | 12              | 4                   | 25               | 647          |
| 2011 | 27              | 7                   | 39               | 1633         |

### 3 Participation in the study and picking procedure

#### 3.1 Assumptions

Within the NMSOP (Chapter 11) one finds general guidelines of how to analyze and pick seismograms. We therefore assume that an analyst is familiar with these techniques and the IASPEI approved standard phase nomenclature (IS 2.1). Moreover, IS 11.4 offers a “Tutorial for consistent phase picking at local to regional distances”. However, we do not want to discourage other possible techniques and **welcome participation from all analysts and automated systems**. In part, the study is to collect the methodology employed in analyzing seismograms and we encourage participants to provide their methodology once they have picked the common data set. This would help in generalizing and spreading the awareness of **best practice** and to identify and avoid in future frequently made mistakes. Since, most routine analysis is performed on events, we understand that not all picks can be associated to a particular phase; the naming of phases will need to be addressed with future work. We are interested in where an analyst records the time of an arrival. This picking process is initially performed on the raw seismograms and only then, if an analyst would like to introduce filtering and waveform enhancement to refine their picks, we will allow these procedures to identify additional biases. Windowing or zooming of the seismogram is encouraged to improve the recognition and timing of onset arrivals.

### 3.2 General procedure

After downloading or receiving the data set, follow the naming convention outlined in Table 2. If you are using a picking program that does not follow this convention, you will need to include a conversion table of the naming convention used when returning your picks. If additional phases are observed, place additional markers as needed and record the observed phase to be reported with the submission of the picks.

**Table 2** Naming convention for picks using SAC header variables.

| SAC header | Arrival type |
|------------|--------------|
| Amarker    | P or Pg      |
| T0         | S or Sg      |
| T1         | Pn           |
| T2         | Sn           |
| T4         | Lg           |
| T5         | Rg           |

In addition to the recorded phase picks from the data set, we record basic information on each analyst. We use the analyst information to derive correlation of picks based on years of experience, average number of seismograms picked in a year, number of seismograms picked in the past six months, institution/organization, and types of seismograms picked (local, regional, teleseismic, explosion). This profile, along with participant names and results, will not be released for comparison of analysts or institutions.

## 4 Results from SPEAR

The most striking result from the experiment is the trend observed in pick difference versus years of experience (Figure 1). The cut-off of having more than five years experience seems to group the analysts with the lowest pick difference and measurement repeatability. This phenomenon of 5 years experience has been observed in other research as the minimum time to achieve expertise in a given skill (Gladwell, 2008). However, we also note that the years experience is not always indicative of how the overall population will pick and further work is needed to clearly identify analysts that have achieved a competent level of picking.

**Figure 1** The years experience of each analyst versus the pick difference calculated from the mean arrival time for S and P picks.

#### 4.1 Pick difference

The goal is to determine the arrival time of all phases recorded and we assume each analyst is measuring the same observation. This assumption has resulted in pick differences over a minute (Figure 2). While for standard locating procedures this magnitude of error would be unacceptable, for our purposes we can identify features in the noise field that cause false detections. In many cases, the observations that are over a minute from the mean arrival time have detections that are within seconds of them; this suggests that multiple analysts observed the same feature in the waveform. When participating in the study we encourage analysts to only record observations they can clearly identify. In every case there is at least one event recorded, but if an analyst is unable to detect a significant arrival, we encourage them to not make any measurements. However, if multiple events are observed or if additional arrivals are observed, we encourage the analyst to time and record these detections. In the case an arrival is misidentified we will correct this type of error and add the observation to the correct population.

The pick difference is calculated from the average arrival time for each common observation. When new data is added the average arrival time is recalculated and a new pick difference is established (Figure 2). Since the true arrival time is known for the synthetic seismograms we also compute the pick error for stations 27-40; pick error for these stations can be calculated as an absolute term (Figure 3). Since, the other stations do not have a known arrival, only a relative pick error can be determined. To establish the reliability of the relative pick error, the synthetic measurements will be compared to the mean pick time (average arrival time measured by the analysts) and the known arrival time.

**Figure 2** The pick differences of P and S phases computed from the average arrival time. The synthetic traces did not have an S phase to pick.

When you compare the analyst made picks on the synthetic seismograms, you see that overall the analysts made similar picks. However, when you compare the analyst picks to the known

arrival time, stations 28, 29, 32, 33, 35 and 38 show a bias of up to 0.5 seconds (Figure 3). All of the late picks are a result of emergent arrivals and analysts choosing to measure the arrival in the coda energy of the phase (the other stations that are biased late are due to the SNR). This presents a difficult variable to the model, since the traditional SNR cannot capture the true amplitude difference between the measured signal and noise.

**Figure 3** The pick difference for the synthetic pulses, (left) based of the pick difference from the mean arrival time and (right) based off the known arrival time.

Additionally we have placed a repeated seismogram in the data set to determine an analyst's repeatability (Figure 4). Overall the analysts are able to repeat their measurements with a high level of precision, with the type of phase measured and the years experience being the main factors influencing repeatability.

**Figure 4** The pick difference between repeated measurements on the same seismogram during the initial round of picking.

The overall goal of the experiment is to derive a pick model based on signal quality. However, no signal quality measurement has been found that adequately models the pick error associated with the process of timing seismic phases. We applied the traditional Short Term Average versus Long Term Average (STA/LTA) using an RMS method of computing the SNR (Figure 5). The STA/LTA model was broke into a two part model of picks with an SNR of 2 or less could have up to a 20 second pick error and all other picks have a pick error

of 0.1 seconds. This model is a bit disappointing because all picks under SNR 2 would be thrown out of location solutions. We tested other models to establish signal quality, however, to keep the focus and brevity of this information sheet, this topic needs to be studied further and reported in additional papers.

The best model we found so far to model the pick error is using the peak average ratio of the Power Spectral Density (PSD) of the signal and noise. This approach is similar to the Wide-Spectral band Ratio (WSR) described in Zeiler and Velasco (2009). The PSD ratio provided a broader window to establish a linear relationship between the lower quality signals and then a general pick error for high quality signals (Figure 5). The PSD ratio shows that a signal 10 times larger in amplitude than the back ground noise can be picked with the highest precision.

**Figure 5** The traditional signal quality of RMS (left) and peak average PSD ratio between signal and noise (right) plotted against the pick error to establish a pick model. The red dashed lines mark the standard deviation of the pick error for the signal quality measurement.

## 4 Summary

To be successful the SPEAR project needs the continued support of the seismological community by picking the common data set (obtained by contacting the authors or downloading from the NMSOP site). The initial results of SPEAR are promising, but we still need more participants to establish the statistical significance of the measurements. Therefore, we invite all interested seismological institutions, data analysis centers and observatories to participate in the SPEAR project. For **user guidelines** see the **Annex**.

Additional work is also needed to establish the best criteria for quantifying signal quality. The initial measurements are crucial to the event location processes along with the process of event refinement and classification. By fully understanding the errors associated with picking, seismological observatories can better tune their automated systems and improve velocity models. Along with these crucial elements a better understanding of achievable location precision can be assessed from the quality of picks. However, the biggest contribution will be to facilitate the sharing of picks for global studies and work load reduction.

## Annex

**SPEAR – User Guidelines**

If you are a single analyst, you can download the data sets via the link [Download programs and files](#) from the NMSOP-2 front page. For institutions with more than 2 analysts that will be participating in the study please contact the author for additional data sets. The data needs to be randomly ordered to prevent any learning bias. Once the data sets have been downloaded follow the guidelines in section 3 of IS 11.5. Also, please do not use any of the results provided in IS 11.5 to influence the method of picking.

Depending on the software that is used to analyze the data, common picking procedures need to be adopted. If you are using SAC the provided shell script will allow you to scroll through and pick the events while recording your picks in an output file. However, if you are using a different program the standard procedure is to review the three component data for each station. Only review one stations data at a time and proceed to the next stations data once all picks have been recorded. Do not return to any of the picks to correct or modify them once you have proceeded to the next station. The only enhancement to the waveforms is zooming or windowing the data. Please mark any phases you can identify (following Table 2 in IS 11.5), whether you can name them or not. Generally there is only one event per station, however, if additional phases are observed please measure the arrival time and report them. Stations 27-40 have only a single pulse to identify. Save the measured arrival times and e-mail them back to the first author: [cpzeiler@miners.utep.edu](mailto:cpzeiler@miners.utep.edu).

Once you have recorded the initial picks, feel free to re-pick the waveforms with any filtering or waveform analysis techniques that are common to your observatory. Send these picks in a separate file with a description of the technique used to record the observations. With the pick files also please submit the following information:

- years of experience
- average number of seismograms picked in a year
- number of seismograms picked in the past six months; institution/organization
- types of seismograms picked (local, regional, teleseismic, explosion)
- identify if you would be willing to re-pick the waveforms in 6 months to a year.

Feel free to contact the author for any additional help or clarification of the procedures.

**Acknowledgment**

The authors would like to thank the analysts that have voluntarily contributed time and energy to pick the common data set. The analysts are highly tasked and their donated time is greatly appreciated. The authors also thank the editor P. Bormann for valuable comments that helped to focus and improve the manuscript as well as his offer to make the SPEAR data set and user guidelines accessible via the NMSOP website.

## 1 Introduction

The purpose of this information sheet is to illustrate the steps involved when analyzing seismic records by means of the SEISAN software. Examples are given for local, regional and teleseismic earthquakes. This is done by giving representative screen plots together with explanatory texts that follow the figures.

For details on the SEISAN software the reader is referred to section 11.4.2 (Data Analysis and Seismogram Interpretation - Software for routine analysis – SEISAN) and the references therein. Details of the software commands are not given here, and the reader is referred to the SEISAN manual for details, which can be downloaded either from NMSOP-2 via the link ‘Download programs and files’ or from <ftp://ftp.geo.uib.no/pub/seismo/SOFTWARE/SEISAN/>.

The events are included with the sample data that is available with SEISAN (from version 9.2).

The main background material provided by NMSOP-2 (<http://nmsop.gfz-potsdam.de>), explaining the methodology behind this information sheet, is:

- CHAPTER 2: Seismic Wave Propagation and Earth Models
- CHAPTER 3: Seismic Sources and Source Parameters
- CHAPTER 5: Seismic Sensors and their Calibration
- CHAPTER 6: Seismic Recording Systems
- CHAPTER 11: Data Analysis and Seismogram Interpretation
- IS 2.1: Standard nomenclature of seismic phases
- IS 3.3: The new IASPEI standards for determining magnitudes from digital data and their relation to classical magnitudes
- IS 11.1: Seismic source location
- IS 11.4: Tutorial for consistent phase picking at local to regional distances
- DS 2.1-2.4: Record examples for local, regional and teleseismic earthquakes and explosions

Note that there are in the following some, only apparent, differences between SEISAN internal nomenclature and procedures and those recommended by the IASPEI standards for measuring magnitudes which do not contradict. While SEISAN mb and IASPEI mb are identical, SEISAN mB corresponds to IASPEI mB\_BB. Similarly holds that SEISAN Ms = Ms\_20 and MS = Ms\_BB. Moreover, IASPEI standards recommend to measure mB\_BB and Ms\_BB on unfiltered broadband velocity traces, however accompanied by the statement that their passband should cover at least the period range within which these two magnitudes should be measured. SEISAN, however, always deconvolves any given actual record so as to simulate for mB\_BB a velocity-proportional broadband response in the period range between 0.2 and 30 s and for Ms\_BB a response in the period range between 3 and 60 s. This allows in SEISAN to read the broadband magnitudes also on short-period records, provided that the SNR is sufficient to allow a broadband velocity restitution.

## 2 Analysis of a local earthquake in southern Norway recorded between 50 km and 650 km epicentral distance

The earthquake chosen here as example occurred in southern Norway and was recorded on the Norwegian National Seismic Network operated by the University of Bergen. The event was recorded on a mix of short-period and broadband seismic stations. It was automatically detected and then interactively processed.

The earthquake parameters are:

|              |                     |
|--------------|---------------------|
| Date:        | 14 Mar 2012         |
| Origin time: | 19:22:27.9<br>(UTC) |
| Latitude:    | 59.526°N            |
| Longitude:   | 5.615°E             |
| Depth:       | 13.9 km             |
| ML:          | 3.4                 |

We now show the step-by-step procedure to analyze the earthquake.

*Vertical-component traces, unfiltered:* Our starting point is a waveform file that is produced by an automatic detection system. No additional information is given, although, depending on the automated processing system, additional information including type of event, location and magnitude may already be available. It is our first task to identify the type of event that is recorded. If the detection is not false, the initial choices are between local, regional and teleseismic event. It may also be possible to identify if the event is likely an explosion based on the characteristics of the waveforms and the pattern of phase arrival times. The above multi-trace plot shows records of a small local earthquake, characterized by the short signal duration of less than about 1 min and a relatively high frequency signal content.

The event is recorded on 13 seismic stations. The numbers on the SEISAN multi-trace plot gives the DC of individual traces on the left and the maximum zero to peak amplitude on the right. The units are counts unless instrument correction is used to compute displacement, velocity or acceleration with the units nm (nanometers =  $10^{-9}$  m), nm/s and nm/s<sup>2</sup>, respectively. Station and component codes are given left of each trace together with the location code and network code. For the first trace, the station is ASK, the component is EHZ (short-period seismometer, with high sampling rate of more than 80 samples per second), the location code is 00 (used to indicate differences between equipment that gives the same component code at the same site, for example an STS2 at 40sps is labeled BHZ.00 and an STS1 at 20sps is labeled BHZ.10) and the network is NS (indicating who operates the station, in this case NS = Norwegian National Seismic Network). The event is well visible on the short-period seismometer records, which have the component code EHZ. However, it is not seen on the broadband traces, which are labeled HHZ, as this is a small earthquake where the signal content is mostly above 0.5 Hz.

*Vertical-component traces, filtered 2-8 Hz:* Applying this high-frequency band-pass filter, which suppresses the more long-period microseismic noise in the broadband records, the earthquake is now clearly seen on all the traces. As compared to the previous plot, the time window of signal arrivals has been cut out and the time scale been stretched. With distinct primary P- and secondary S-wave arrivals in this frequency band it is very clear that this is a local earthquake. We can see from the arrival times that the earthquake was closest to station BLS5. In SEISAN we then put this event into the database and start the processing.

*Single trace plot of station ASK at epicentral distance of 109 km, unfiltered:* In SEISAN, we mostly do the phase picks on single trace plots, like shown here, or on three-component trace plots. For this recording on a short-period seismometer it is not necessary to filter the data in order to pick phase arrivals. The P arrival is marked.

*Single-trace plot of station ASK at epicentral distance of 109 km, unfiltered:* This is the same station as on the previous plot, but this time we have zoomed in on the P arrival. It is now possible to read the P arrival time more accurately, and we can also identify the polarity of the first arrival, which is compression (upward motion on the vertical component) in this case. The phase arrivals will be used for the earthquake location (see IS 11.1) and the polarity can be used to determine the fault plane solution (see also EX 3.2).

*Three-component trace plot of station ASK at epicentral distance of 109 km, unfiltered:* We normally read the S arrival on one of the two horizontal channels and not on the vertical as SP conversions may arrive prior to S and result in an incorrect reading of the onset time.

*Single-trace plots of station ASK at epicentral distance of 109 km, Wood-Anderson filter:* To read the ML amplitude, the instrument response is removed and a filter equivalent to the revised Wood-Anderson seismograph response according to Uhrhammer and Collins (1990) (see also IS 3.3) is applied. The bottom trace is a zoomed-in version of the area between the two vertical lines on the top trace. In SEISAN the amplitude is given in units of nanometer. It is measured peak-to-adjacent trough of the maximum deflection of the seismogram trace, where peak and trough are separated by one crossing of the zero-line (sometimes described as “peak-to-peak amplitude”) but stored in the database is peak-to-peak/2 according to the IASPEI (2013) standard. This maximum amplitude is normally read from the S or Lg waves. It is stored as the IAML amplitude phase. ‘I’ stands for IASPEI standard, assuring that the standard Wood-Anderson filter response and the recommended amplitude measurement procedure has been applied (see IS 3.3), and ‘A’ stands for displacement amplitude in nm. IASPEI standard for ML is to measure A on horizontal components. In Norway, however, it is routine practice to use the vertical component for the amplitude reading of ML and the scale given by Alsaker et al. (1991; see also DS 3.1, Tab. 2). This scale was derived for Norway and scaled so that its results match at 60 km distance with those of the horizontal component California standard formula for equal IAML input (see next figure and recommendations in IS 3.3). The default ML formula implemented in SEISAN is that of Hutton and Boore (1987; see next figure and formula in DS 3.1, Tab. 2), on which also the IASPEI standard formula for ML is based (see IS 3.3). If, however, this default procedure is used in other regions with other attenuation conditions then the calculated ML values may differ from standard ML. DS 3.1. Table 2, offers several ML calibration functions for other regions together with comments on their scaling, components to be used and the distance range of their applicability. You may implement in SEISAN either your own properly to the ML standard scaled local calibration function, or, if not yet available, one of those which you believe to match best with the seismotectonic conditions in the area. Note, however, that local ML data based on not yet tested and proven standard scaling should not be published with the nomenclature for standard ML. That is, why we use in NMSOP *M<sub>l</sub>* as the general nomenclature for local magnitude, and *M<sub>L</sub>* only for *M<sub>l</sub>* that has been properly scaled to the new standard. Otherwise, users of local magnitude data do not know whether or not they have been correctly scaled according to the now globally set standard. E.g., according to Braunmiller et al. (2005) (see also section 3.2.9.6 in the forthcoming new Chapter 3) the *M<sub>l</sub>* scales used by various agencies in Southern Germany, France, Italy and Switzerland yield results for equal input data that differ on average between 0.2 to 0.6 m.u. when scaled to *M<sub>w</sub>*.

Some examples for other regional ML calibration functions have been plotted in the diagram below. Note that the Alsaker et al. (1991) scale (lowermost full line) for the continental shield areas of Scandinavia and Eurasia reveals significantly lower attenuation when compared with Southern California calibration curves of both Richter (1935) and Hutton and Boore (1987) (see full dot and open dot curves in the Figure below). Accordingly, since properly scaled to the latter at about 60 km epicentral distance, the Alsaker et al. calibration curve yields at several 100 km distance for equal amplitude input data already ML values that are several tenths of magnitude units smaller than those derived by applying the original Richter scale. This difference increases to 1.7 m.u. at a distance of 1500 km, up to which the Alsaker et al. (1991) scale is defined (although strictly Hutton and Boore (1987) is limited to 600 km).

We now repeat the same procedure of measuring IAML for the other stations, however show only examples from some selected stations to explain specific aspects of the data processing.

*Three-component traces of station BLS5 at epicentral distance of 49 km, unfiltered:* Plotted are the three-component broadband traces from the nearest station. P and S arrivals, and the ML amplitude were read. In this case the SNR was high enough so that it was not necessary to filter the broadband recordings to identify the phase arrivals.

Three-component traces of station DOMB at epicentral distance of 342 km, unfiltered: Going to larger distances, the signal amplitudes at higher frequencies decrease relative to the more low-frequency microseismic noise, which peaks around 5 seconds. Here, we would normally filter the traces to read the phase arrivals.

Three-component traces of station DOMB at epicentral distance of 342 km, filtered 3-8 Hz: For this station, it is possible to read besides the larger amplitude P and S arrivals, termed Pg and Sg, additionally the commonly weaker but earlier arrivals Pn and Sn. In SEISAN we generally mark the first P- and S-wave arrivals as P and S, respectively. The location program then determines which phase arrives first. Sometimes, Sn (here marked as ES) is weak and not recognizable in the signal-generated noise of scattered P waves. Then one has to mark Sg as such, since the location program otherwise would use it as the first arriving S (Sn in this case).

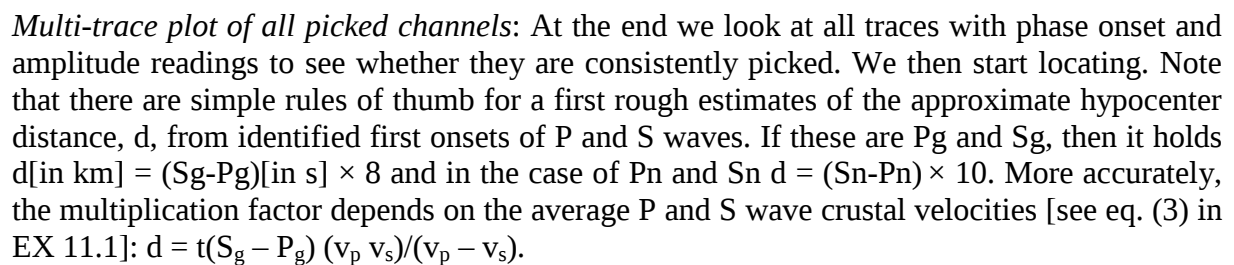

Reading different phases with different take-off angle from the source, such as Pg/Pn and Sg/Sn, significantly improves the depth determination. However, one should be quite certain that these identifications are correct. This requires fairly clear arrivals, an experienced analyst and that the phases match the solution when locating. For standard nomenclature, nature and travel paths of crustal phases see IS 2.1 and for many more record examples DS 11.1.

Three-component traces of station FOO at epicentral distance of 233 km, filtered 3-8 Hz: This is an example where Sn cannot be read, and S has to be read as Sg.

Single-trace plot of station NSS at epicentral distance of 649 km, filtered 5-10 Hz: Going to larger distances, the P arrival becomes more emergent and would not be read without applying a filter.

*Output from location program:* We use a standard linearized inversion program (HYPOCENTER, Lienert et al. (1986, 1995)) to locate the event that makes use of the common seismic phases at local distances. The location program tries to minimize the differences between the observed (t-obs) and calculated arrival times (t-cal) that are computed for a 1D layered model. The residuals are given in the column labeled 'res'. For our example event these travel-time residuals are relatively small. Note that for station DOMB the residuals are given for both Pn/Pg and Sn/Sg and that our interpretation fits the solution.

Direct (Pg and Sg) and critically refracted wave types (Pn and Sn) were very clearly visible from this earthquake on the records of several stations. This helped to constrain the earthquake depth, which was estimated to be 13.9 km (see last but one line). At the end the location procedure the program gives the magnitude values for the individual components and stations, and calculates the average, which is 3.4 in this case. The text 'LBER' refers to the magnitude type (L for ML) and the reporting agency (BER = Bergen). Some spread in the magnitude residuals (difference between single-component magnitude and average) is expected and mostly due to local site effects. In our case the largest residual are -0.6 and +0.4 magnitude units.

A number of polarities were read, 7 compressional (C) and 4 dilatational (D), which are given in the column after the phase name read and the phase used by the location program. For example, in the second phase line of the location output for stations BLS5, the first phase arrival was read as P, the location program decides that this is the direct Pg arrival based on the hypocentral distance. The polarity is read as D, standing for down or dilatation. The location program computes the azimuth (azm) and angle of incidence (ain), which in this example are 103.3° and 96.7°, respectively. The polarity data can be used to determine the fault plane solution if there are sufficient observations. In this example we can not find a robust solution and do not show the procedure here.

The velocity model used is given by the following table:

| <i>Depth of top of layer in km</i> | <i>P-wave velocity in km/s</i> |
|------------------------------------|--------------------------------|
| 0                                  | 6.2                            |
| 12                                 | 6.6                            |
| 23                                 | 7.1                            |
| 31                                 | 8.05                           |
| 50                                 | 8.25                           |
| 80                                 | 8.5                            |

**Wadati diagram:** To check our readings we can plot the Wadati diagram (plotting S-P times against absolute P arrival times (labels on x-axis given to show scaling), and the data points should fall onto a line like in this example. Data points (+) that are significantly off the line should be checked and re-read.

*Travel time plot:* We can also produce a simple travel-time plot that shows the observations (+) together with the calculated travel-time curves for P and S first arrivals according to the local velocity model implemented in the SEISAN location program (solid lines). For distances greater than about 150 km, our Pg (around the lower curve) and Sg arrivals (around the upper curve) come in mostly after the predicted first arrivals.

Note that SEISAN uses layered 1D velocity models and the user needs to enter the model for his or her respective area. SEISAN allows the use of a number of 1D models for events depending on their location to account for changes in structure within the area of interest or network coverage.

Source spectrum plot for station BLS5 at epicentral distance of 49 km: We compute the source displacement spectrum (upper curve in the bottom diagram above the noise spectrum) for the vertical component of this station. The spectrum is corrected for attenuation, which for Norway is given by  $Q(f) = 440 \times f^{0.7}$  (see data at bottom right). From the spectrum we can approximately read the long-period spectral level, which is translated via the assumed velocity and density model into seismic moment (here  $\log_{10}M_0 = 13.47$  Nm) and moment magnitude ( $M_W = 2.9$ ). We also measure the corner frequency ( $f_c = 10.8$  Hz), which is translated into stress drop  $\Delta\sigma = 68.8$  bars = 6.88 MPa using  $\Delta\sigma = (7/16) M_0/R^3$  (Eshelby, 1957).

Source spectrum plot for station FOO at epicentral distance of 233 km: The spectral analysis is normally done for a number of stations with good SNR. When comparing the results for this station with those of the previous station (BLS5) one finds the difference between the moment magnitudes to be small, but the stress drop difference to be large because of the reading uncertainty in  $f_c$  and  $\Delta\sigma \sim f_c^3$ . (For related formulas and discussions see EX 3.4). At the end, the averages are computed from all observations and standard deviations are calculated.

*Location maps in GoogleEarth:* SEISAN creates files that make it possible to look at the location with GoogleEarth immediately. The figure on the left shows the epicenter area with the error ellipse plotted as a solid black line. The extent of the 90 percent confidence error ellipse is about 2.5 by 9.0 km. It is also possible to compare the epicenter location to known fault structures. In the case of explosions we try to see if the event is located close to a known mine or quarry.

On the right, we show a more regional GoogleEarth map, which shows the epicenter as a red dot. The stations are color coded depending on their residual from the hypocenter location where green is low residual, yellow is moderate residual and red is high residual (the color levels are configurable). In this example, there are no stations towards the west and southwest of the epicenter and stations are sparse toward the southeast, resulting in an azimuthal gap of 216 degree. This, together with the dominating N-S extension of the Norwegian network causes the much larger location uncertainty in E-W direction (see error ellipse in the left-hand panel). We can also plot the epicenter together with previously located earthquakes.

### 3 Analysis of a regional earthquake recorded at distance between 440 and 2950 km ( $\Delta < 30^\circ$ )

As an example we have chosen an earthquake that occurred on the Mohns Ridge, offshore northern Norway. The earthquake with a magnitude greater than 6 was large enough to be recorded globally. Here, we process data that were recorded on the Norwegian National Seismic Network operated by the University of Bergen and data provided by IRIS from the Global Seismograph Network (GSN). All data used here was recorded on broadband stations.

The earthquake parameters provided by the USGS are:

|              |                     |
|--------------|---------------------|
| Date:        | 24 May 2012         |
| Origin time: | 22:47:46.6<br>(UTC) |
| Latitude:    | 72.99°N             |
| Longitude:   | 5.65°E              |
| Depth:       | 8.8 km              |
| Mw:          | 6.2                 |

We now show the step-by-step procedure to analyze the earthquake.

*Vertical component multi-trace plot, unfiltered:* On the seismograms we clearly see long-period surface waves, with large amplitudes and pronounced dispersion. This indicates that the earthquake is relatively large and shallow. For the stations, where we see the first arriving P as well we can estimate the approximate distance from the time difference between the P and the Rayleigh surface wave maximum (which is most pronounced in vertical component records). For station BFO this time difference is about 10 min. According to Table 1 below this means that station BFO is about 20 to 25° degrees away ( $1^\circ = 111.2$  km) from the epicenter. Being aware of the station locations, considering the pattern of arrival times, and,

if three-component records are available, also of the first-motion polarity patterns and the better constraining S-P travel-time differences, we can also get a first guess of the epicenter location (see EX 11.2).

**Table** Approximate time interval ( $t_{Rmax} - t_p$ ) between the arrival of the maximum Rayleigh wave amplitude and the first onset of P waves as a function of epicentral distance  $\Delta$  according to Archangelskaya (1959) and Gorbunova and Kondorskaya (1977) for dominantly continental travel paths.

| $\Delta^\circ$ | $t_{Rmax} - t_p$<br>(min) | $\Delta^\circ$ | $t_{Rmax} - t_p$<br>(min) | $\Delta^\circ$ | $t_{Rmax} - t_p$<br>(min) |
|----------------|---------------------------|----------------|---------------------------|----------------|---------------------------|
| 10             | 4-5                       | 55             | 26                        | 100            | 45-46                     |
| 15             | 6-8                       | 60             | 28-29                     | 105            | 47-48                     |
| 20             | 9-10                      | 65             | 31                        | 110            | 48-50                     |
| 25             | 10-12                     | 70             | 33                        | 115            | 53                        |
| 30             | 13-14                     | 75             | 35                        | 120            | 55                        |
| 35             | 15-16                     | 80             | 37                        | 125            | 57                        |
| 40             | 18-19                     | 85             | 39-40                     | 130            | 60                        |
| 45             | 21                        | 90             | 42                        | 140            | 64                        |
| 50             | 24                        | 95             | 43                        | 150            | 70                        |

*Vertical component multi-trace plot, filtered 0.01-0.1 Hz:* Filtering the data at low frequencies, we see both body and surface waves. However, the seismograms are dominated by the surface waves as they have larger amplitudes in this frequency range. The shape of the surface wave trains depends on the Earth structure along the paths (see, e.g., Chapter 2, Figs. 2.10, 2.12 and 2.13) and, because of the dispersion, i.e., the dependence of the surface-wave velocity on the period, also on the epicentral distance (see Figure above). The seismograms also depend on the mechanism of faulting.

*Multi-trace plot, filtered 1-5 Hz:* Looking at higher frequencies, the surface waves disappear from the seismogram and we look at P and (at these high frequencies and in vertical component records usually less clear) S body waves. If the first arriving P and S phases are  $P_n$  and  $S_n$ , respectively, then there is a simple “rule of thumb” to estimate the hypocenter distance, namely time difference  $S_n - P_n$  [in s]  $\times 10$ . For station LOF with a time difference of about 1 min this means a distance of  $\approx 600$  km. This agrees with the rough estimate from the time difference between the Rayleigh-wave maximum and the P first arrival. On some stations (STEI, TRO and LOF) we can also see a signal in this frequency range arriving much later (about 5 minutes after P for station TRO). This is the T(tertiary)-wave, generated by an earthquake in or near the oceans, propagating in the oceans as an acoustic wave and converted back to seismic wave at the ocean-land boundary near the recording site. (for more explanations see Chapter 2, section 2.6.5). It should not be mistaken for another event.

*Three-component traces of station SPA0 at epicentral distance of 648 km, unfiltered:* Zooming around the P arrival the phase can be picked with or without filter. The error on the phase reading here may be as large as 0.5 sec.

*Three-component traces of station LOF at epicentral distance of 603 km, filtered 1-5 Hz:* Looking at this coastal station, we clearly see the arrival of the T wave. The amplitude of the T wave is in this case comparable to the S-wave amplitude. According to the time difference (S-P)[in s]×10 the station is about 600 km away from the source.

*All vertical traces, unfiltered:* The traces are sorted by distances and the P arrival picks are shown. This type of plot is useful to check the consistency of the picks. Based on the P arrival times, the epicenter is estimated at 73.055°N and 5.856°E. The hypocenter depth is not constrained by the data and given as 0 km by the location program. On stations like SPA0 we can see that we have both high and low frequency. Towards larger distances the high frequencies get attenuated more strongly than lower frequency signals.

*All vertical traces, filtered 3-8 Hz:* We can see that the signal amplitude of the higher frequencies decreases as we go to larger distances due to attenuation. The distance range here is approximately 440 km (station BJO1) to 2960 km (station ARU).

*Selected vertical traces, filtered 2-6 Hz:* Computed Pn and Sn phase arrival times have been marked by red vertical lines and the text 'yPn' and 'ySn'. No S-waves are recognizable in the records of the two stations BJO1 and HSPB closer to the epicenter. They are likely situated in an azimuth range of minimum S-wave and strong P-wave radiation (see EX 3.2). While S appears at larger distances, the phase is emergent and from this plot its travel-time does not match well with the global velocity model used (IASP91). The earthquake is located on the Mid-Atlantic Ridge. The seismograms are complicated both due to source and path effects, including the transition from oceanic to continental crust. The display of theoretical arrivals should only serve as a guide on whether the considered phase is plausible to arrive in this time window. However, it would be **wrong** to pick a phase close to the predicted time if there is no visible change in the signal.

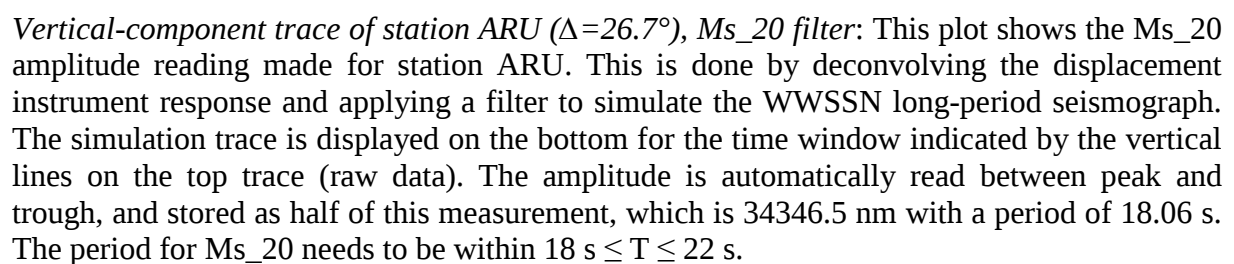

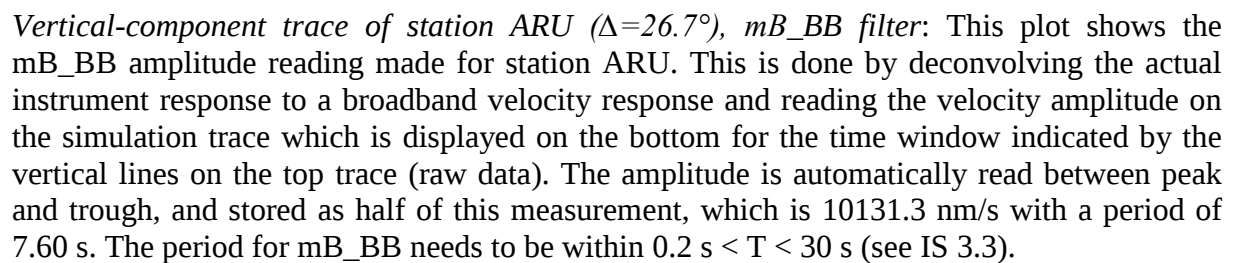

*Three-component trace plot of station MOR8 at epicentral distance of 813 km, filtered 1-5 Hz: This is an example where the S arrival can be read quite well on one of the horizontal channels.*

*Vertical-component trace of station ARU ( $\Delta=26.7^\circ$ ), mb filter: While it is possible to read ML amplitudes from this earthquake for stations within about 1500 km, this is not done because the ML scale for Norway is not appropriate for sources on the Mid-Atlantic Ridge. We, therefore, read amplitudes for the teleseismic magnitudes which can be used down to distances of  $20^\circ$  and even down to  $2^\circ$  for standard  $M_s$ \_BB. Moment magnitude for this event can be measured using either regional or teleseismic moment tensor inversion (USGS  $M_w = 6.2$ ). The plot above shows the mb amplitude reading for station ARU. This is done by deconvolving the broadband instrument response and applying a filter to simulate the WWSSN short-period seismograph (see IS 3.3). The simulation trace is displayed on the bottom trace for the time window indicated by the vertical lines on the top trace (raw data). The amplitude  $I_{amb}$  is automatically read between the largest peak and adjacent trough. It is stored as half of this measurement, which is 195.2 nm, together with the related period  $T$  of 0.90 s which is twice the time difference between peak and trough.*

*Vertical-component trace of station ARU ( $\Delta = 26.7^\circ$ ),  $Ms\_BB$  filter:* This plot shows the  $Ms\_BB$  amplitude reading made for station ARU. If the primary record is not yet a velocity broadband trace then the latter has to be synthesized by deconvolving the actual instrument response to a broadband velocity response and reading the velocity amplitude on the simulation trace. The latter is displayed on the bottom trace for the time window indicated by the vertical lines on the top trace (raw data). The amplitude is automatically read between the largest peak and adjacent trough, and stored as half of this measurement, which is 16468.0 nm/s, together with a period of 16.10 s, i.e., twice the time difference between the peak and adjacent trough. The period needs to be within  $3 \text{ s} \leq T \leq 60 \text{ s}$ , and thus maybe significantly shorter than for  $Ms\_20$  measurement, allowing  $Ms$  measurements at distances well below  $20^\circ$  (down to  $2^\circ$ ).

Based on these four amplitude and period measurements from station ARU, we can compare the magnitudes to  $M_w$ :

| Magnitude scale | Value |
|-----------------|-------|
| $M_w$ (USGS)    | 6.2   |
| mb              | 5.9   |
| $mB\_BB$        | 6.7   |
| $Ms\_20$        | 6.0   |
| $Ms\_BB$        | 6.1   |

We see that the values for this size of earthquake around magnitude 6 compare well, with the exception of  $mB\_BB$  which is on global average about 0.3 -0.4 m.u. greater than  $M_w$  at  $M_w = 6.2$  and about 0.6 m.u. larger than mb.

Vertical-component trace of station TRO at  $\Delta = 5.3^\circ$ ,  $M_s_{BB}$  filter:  $M_s_{BB}$  can be used down to distances of  $2^\circ$ . This plot shows the  $M_s_{BB}$  amplitude reading made for station TRO. The amplitude is automatically read between peak and trough, and stored as half of this measurement, which is 108113.5 nm/s with a period of 21.92 s. The computed magnitude is  $M_s_{BB} = 5.7$ , compared to  $M_s_{BB} = 6.1$  for station ARU.

*Output from location program:* We use the same standard linearized inversion program (HYPOCENTER) to locate this event as used for the local event. The location is based on the IASP91 global travel-time model. The residuals are much larger than for the local event as the difference between the true regional model and IASP91 is significant. The largest residual here is more than 3 seconds. In the hypocenter determination we fixed the depth to 8.8 km and, using both P and S readings, we obtain a latitude of 72.943°N and longitude of 6.096°E. This compares to 73.055°N and 5.856°E for the preliminary location based on P arrivals only. The solution based on P and S is 15 km east of the USGS solution.

Based on all our amplitude and period measurements the following network average magnitude values were calculated:

| Magnitude scale | Value |
|-----------------|-------|
| Mw (USGS)       | 6.2   |
| mb (USGS)       | 5.7   |
| mb              | 6.4   |
| mB_BB           | 7.0   |
| Ms_20           | 6.3   |
| Ms_BB           | 6.1   |

Note that Ms\_20 and Ms\_BB are within 0.1 m.u. of the USGS Mw. In contrast, both our mb and mB\_BB are significantly larger, with mb, based on only 4 measurements in the near teleseismic distance range between 2000 and 3000 km, even by 0.7 m.u. larger than USGS mb, based on 299 measurements at a much larger range of distances up to about 11,000 km. This may hint to larger calibration uncertainties of the Gutenberg-Richter (1956) Q function in the near teleseismic distance range, where wave propagation is largely influenced by the greater inhomogeneity of upper mantle wave propagation and attenuation. This may result in larger uncertainty of body-wave magnitude estimates, if they are available in only very limited number in the near teleseismic range. On the other hand, this earthquake has taken place on the North-Atlantic Ridge (see Google map below). Intra-oceanic ridge strike-slip earthquakes are often high stress drop events characterized by a much larger than average ratio of  $E_s/M_0$  and thus much larger  $M_e$  than Mw (e.g. Bormann and Di Giacomo, 2011; Choy, 2012, in IS 3.5). Then, mb and mB\_BB may be much larger than usual too in their relation to long-period Mw and Ms. Therefore one might consider this as an alternative explanation, which is, however, neither supported by the much more representative USGS mb value (being rather normal for Mw = 6.2) nor by the relatively long and not very impulsive P waveforms. The latter are, in the case of high stress drop events, expected to be relatively short, impulse-like and of more high-frequency content (e.g., Fig. 3.6 in Chapter 3). Instead, the P-wave group is rather long for an Mw6.2 event, almost one minute, and relatively long-period.

*Location map in GoogleEarth:* This map shows the location with its error ellipse on the Mid-Atlantic ridge and the stations that were used for the analysis and location.

## 4 Analysis of a shallow earthquake recorded at teleseismic distances ( $30^\circ < \Delta < 90^\circ$ )

The earthquake chosen here as an example occurred in Russia at a shallow depth of 10 km (according to USGS). We extracted data from IRIS that was recorded on the Global Seismograph Network (GSN). All data used here were recorded on broadband stations.

The earthquake parameters provided by the USGS are:

|              |                  |
|--------------|------------------|
| Date:        | 14/02/2013       |
| Origin time: | 13:13:53.1 (UTC) |
| Latitude:    | 67.61°N          |
| Longitude:   | 142.60°W         |
| Depth:       | 10 km            |
| Mw:          | 6.9              |

We now show the step-by-step procedure to analyze the earthquake.

*Multi-trace plot of vertical components, unfiltered:* Record durations up to about 60 minutes at some stations and the observation of much larger surface-wave than body wave amplitudes hints to a large shallow earthquake at teleseismic distances.

*Output from the location program:* Locating with the first P arrivals only, we obtain an epicenter location (67.522°N, 142.826°W) and depth = 0 km that is very close to the one given by the USGS. The depth is not constrained with the teleseismic P arrivals only.

*Multi-trace plot of vertical components, unfiltered:* Plotted are the traces on which we have read the initial P. Based on the hypocenter obtained, we compute the synthetic arrival times of all phases. The traces are sorted by distance. The phases PP, S and SS are clear on all traces. We will now read the onset times of all these phases (plus P-wave first motion polarity), run the location program again with this additional information and see how the location changes.

*Three-component trace plot of station PASC at  $\Delta=62.2^\circ$ , unfiltered:* For this station P on the vertical component and S on the N component are very clear. Other phases are not very clear. Note that we do not pick the onsets at the calculated arrival times (red bars) but only at the distinct onset of the real phases with large SNR (black bars).

*Three-component trace plot of station PFO at  $\Delta = 63.3^\circ$ , filtered 0.02-0.1 Hz:* At this distance there is sufficient separation between S and SKS<sub>ac</sub> to read both phases. The component codes of the horizontal components here are BH1 and BH2 to indicate that the instrument is not exactly aligned with the geographic directions. In this case, the direction of orientation is given with the component's metadata and can be used to rotate into a NS-EW system.

*Output from the location program:* Using additional phases the location changes slightly, but without readings of depth phases or P-wave onsets very near to this shallow source the depth cannot be better resolved compared to the USGS.

*Vertical component traces of stations KBS and KDAK, unfiltered:* We try to read first-motion P-wave polarities (upward motion = C = + = compressional, downward motion = D = - = dilatational) which can allow us to estimate a fault-plane solution for this earthquake. For station KBS (top) it is possible to read the polarity, which is upward (compression). For station KDAK it is not possible to read the polarity, although we were tempted to read this as a downward motion (dilatation). As seen further down, the selected data set does not have stations that are for sure in a dilatational quadrant, however, the position of all our compressional readings (see next figure) are in agreement with Global CMT fault-plane solution.

The following solution was provided by the Global CMT catalog ([www.globalcmt.org](http://www.globalcmt.org)) for this event. The solution shows an oblique thrust mechanism:

### 201302141313A EASTERN SIBERIA, RUSSIA

Date: 2013/ 2/14 Centroid Time: 13:13:58.6 GMT

[Lat= 67.71](#) [Lon= 142.62](#)

Depth= 12.0 Half duration= 5.2

Centroid time minus hypocenter time: 5.5

Moment Tensor: Expo=26 1.030 -0.627 -0.404 0.335 0.075 0.729

Mw = 6.7 mb = 0.0 Ms = 6.6 Scalar Moment = 1.2e+26

Fault plane: strike=327 dip=42 slip=115

Fault plane: strike=115 dip=52 slip=69

*Fault-plane solution plot:* This plot is created in SEISAN and shows the solution given by the Global CMT catalog together with polarities read from the example. We can see that all our observations lie near the center of the focal sphere and are likely compressions. However, the readings we made show compression and dilatation, and most likely the dilatational readings are wrong. Although looking at more than 100 stations from the global networks, we do not have good enough coverage of the focal sphere as all our rays to teleseismic stations only leave the source downward near the vertical. In contrast, the moment tensor solution (based on full waveforms from P, S and surface waves) normally requires only few stations to obtain a good solution. Using complementary to first-motion polarity readings in SEISAN also S/P amplitude ratios for better constraining fault-plane solutions is possible for local and teleseismic earthquakes. While the use of amplitude ratios did not help with this example, Figure 7.26 in Havskov and Ottemöller (2010) gives an example of teleseismic fault plane solution using amplitude ratios. The polarity readings made by us on individual station records (open circles = C, triangles = D) are given on the side with a link to the azimuth and angle of incidence of the corresponding phase projected onto the focal sphere.

Finally, we demonstrate the magnitude determinations for this earthquake:

Traces of station ANTO at  $\Delta = 60.3^\circ$ , mB\_BB filter: First we read amplitudes for mb and mB\_BB. Measured are the largest P-wave amplitude prior to PP, depth phases of P included, on the vertical component of simulated short-period WWSSN, respectively velocity broadband records. The position of the earlier Iamb measurement has been plotted here on the mB\_BB filtered trace only for comparison by a red arrow-bar. Details of teleseismic body-wave magnitudes are given in the regional event example in section 3 above and in IS 3.3.

Traces of station ESK at  $\Delta = 54.4^\circ$ , Ms\_BB filter: Next we determine the two IASPEI standard surface-wave magnitudes. The bottom trace shows the reading position of the Ms\_BB amplitude IVMs\_BB (black arrow-bar) on an instrument corrected broadband velocity trace.

The top trace is unfiltered and shows the time selection for the bottom trace. Note that the IAMS\_20 amplitude has already been read on another, WWSSN-LP filtered, record, before. However, the position of its measurement is shown here too for comparison (marked by a red arrow-bar). While the largest Ms\_20 displacement amplitude has a period of 21 s, the period of the 10.5 min later arriving largest Ms\_BB velocity amplitude is 11.80 s only. For more details on the determination of teleseismic surface-wave magnitude see the regional event example in section 3 as well as IS 3.3.

Computing the average magnitudes from all amplitude observations we get the values below:

| <b>Magnitude scale</b> | <b>Value</b> |
|------------------------|--------------|
| M <sub>w</sub> (USGS)  | 6.9          |
| m <sub>b</sub>         | 6.7          |
| m <sub>B_BB</sub>      | 7.3          |
| M <sub>s_20</sub>      | 6.9          |
| M <sub>s_BB</sub>      | 6.9          |

In this case the surface wave magnitudes Ms\_20 and Ms\_BB agree perfectly with Mw(USGS) and are equal amongst each other although Ms\_BB has been measured at a much shorter period and a later time than Ms\_20. mB\_BB is significantly larger than mb, and somewhat larger than the two Ms and the Mw magnitude, as expected for earthquakes of Mw = 6.9 according to Utsu (2002) and Fig. 3.70 in section 3.2.9.1 of the forthcoming revised Chapter 3).

The amplitudes and periods that were read for computing the magnitudes are summarized in the following table. Note that here the abridged internal magnitude nomenclature used in SEISAN stands for: mb = mb, mB = mB\_BB, Ms = Ms\_20 and MS = Ms\_BB.

Map showing the epicenter (red star) and stations (blue triangles) used here.

## 5 Analysis of an intermediate depth earthquake at teleseismic distances

The earthquake chosen here as example occurred in Colombia at an intermediate depth of 129 km (depth by USGS). We extracted data from IRIS that were recorded by the Global Seismograph Network (GSN). All data used here were recorded on broadband stations.

The earthquake parameters provided by the USGS are:

We now show the step-by-step procedure to analyze the earthquake.

*Three-component trace plot of station BFO at  $\Delta = 86.4^\circ$ , unfiltered:* Looking at one of the stations, we can see that we are dealing with an earthquake at teleseismic distance as the record shown extends to almost one hour. The seismograms show very clear body-wave phase arrivals, which we will try to identify. The lack of more long-period and dispersed surface waves, however, points at a deep hypocenter. We will start to pick first P arrivals to get an initial estimate of the location, then we try to identify depth phases and other later phases for improved hypocenter determination and finally we use the 3-component record of station BFO only for a single-station event location.

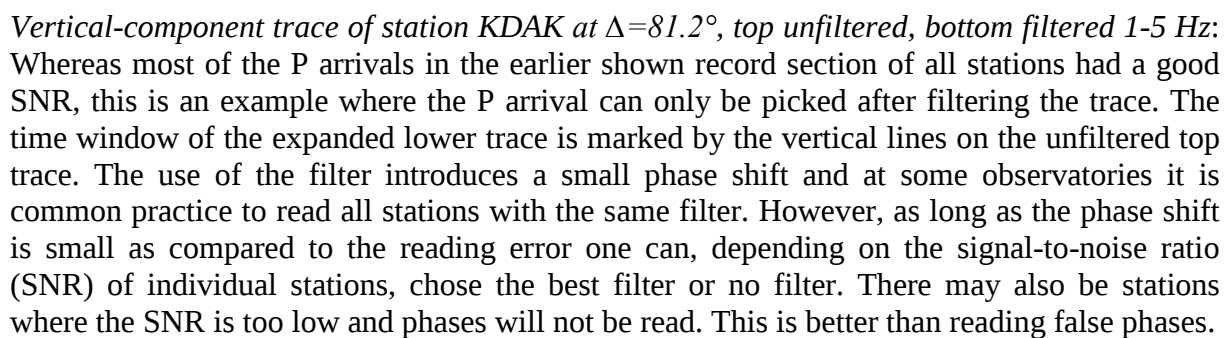

*Multi-trace plot of vertical components, unfiltered:* Shown is only a selection of the stations that are part of the sample data set for this event.

*Vertical-component traces for which phases are picked, filtered 0.02-5 Hz:* These traces are sorted by epicentral distance, ranging from  $30.7^\circ$  to  $162.7^\circ$ . Beside the P first arrival, at some of the traces also clear later arrivals have been marked and identified. Note that from station KURK downward the strong delay of the first arriving longitudinal waves is due to the Earth core shadow for direct P waves. In fact, the group of later arrivals, annotated here as P, relate to different branches of PKP core phases and likely also their depth phases. Also note several distinct onsets following within the first minute after the P onset and well before the arrival of PP. For a first event location we will only use the P and PKP first arrivals. Later, we will zoom into the first few minutes of records in order to find depth phases of P and PKP.

*Output from the location program on the previous page:* Locating with the first P arrivals only, we obtain a hypocenter location (1.183°N, 77.377°W and depth = 132.4 km) that is very close to the one given by the USGS. The depth estimate is perhaps better than expected in this case without the use of depth phases. However, we will now try to use the depth phases we noticed on a number of seismograms. We have so far read all first arrivals as P. The location program determines which phase arrives first. In our example we have P (until station KEV), Pdif (station BILL) and PKPdif (from station KURK onward).

*Vertical-component trace for station BFO at  $\Delta = 86.4^\circ$ , unfiltered:* For this station we have computed synthetic arrival times based on our initial location, which are marked with red bars. We can see distinct phases arriving near the computed pP, sP and PP times. The bottom trace shows the picking of pP about 4 s after the predicted arrival, but there is no clear new energy arrival around the expected sP onset. Note, however, that sP may sometimes be even a stronger phase than pP. The amplitude relationship between these two depth phases depends on the radiation pattern of the source mechanism, which is different for P and S waves (see Chapter 3, section 3.4.1, Figs. 3.100-104), and on the different take-off angles of pP and sP from the source (see Chapter 2, section 2.6.3 with figures). From the measured travel-time difference of 38.2 s between pP and P we estimate a source depth of about 150 km, some 20 km deeper than the source depth calculated by the USGS.

*Three-component trace of station CHTO at  $\Delta = 160.0^\circ$ , unfiltered:* Knowing from the first location of the earthquake that the station is  $160^\circ$  away the first arrival at 35m50s is clearly not P, as originally marked, but PKPdf. The larger onset about 5 s later is a second phase of the same event, yet the much stronger sharp wave onset at about 36m28s is obviously the depth phase pPKPdf and the onset at about 36m45s the depth phase sPKPdf. Note that the travel-time difference pPKPdf-PKPdf of 38 s perfectly agrees with the time difference pP-P = 38.2 s measured at station BFO. Note that the differential times such as pP-P and sP-P should be near constant over a distance range.

*Vertical-component trace for station KMI at  $\Delta=154.0^\circ$ , unfiltered:* In this example we can see onsets that relate to the different travel-time branches of PKP. The corresponding depth phase times are also shown and phases are visible. Core phases are often most clear in the frequency band 1-5 Hz.

*Three-component traces for station BILL at  $\Delta = 98.6^\circ$ , rotated and filtered 0.01-0.1 Hz:* The two horizontal components have been rotated into radial and transverse components using a backazimuth of  $65^\circ$ . SKS has been back-converted from a P wave through the outer core, termed K, into an S wave through the mantle and is, therefore, polarised in the vertical plane of propagation. Accordingly, it has its largest amplitude in the radial component R (middle trace) and not on the transverse component T. It is also visible on the vertical component. This is not the rule for teleseismic S and illustrates that rotating seismograms can be useful in identifying seismic phases (see Figs. 11.16, 11.48 and 11.67 in Chapter 11 of NMSOP-2, Bormann et al., 2013). Having an array of stations, the different apparent velocities of seismic phases can also be used for identification (see, e.g., Chapter 9, and for the identification of core phases Fig. 11.46).

*Output from the location program:* Adding three pP phases and one pPKPdf and sPKPdf each, the hypocenter depth changes (shown in the third and last line) from 132 to 149 km. While this is now more different from the solution given by the USGS, we take this as the best solution determined from our data set, which may be even better than the USGS solution, because the latter commonly uses only P-wave first arrivals for their hypocenter location. Yet, the reading, proper identification and time picking of later arriving phases is crucial for significantly reducing the errors in hypocenter depth estimates (see Figure below).

**Left:** hypocenter locations using only P phases; **middle:** by adding S phases; **right:** by adding also depth phases and core reflections. (Copy of Figure 7 from IS 11.1, modified from Schöffel and Das, J. Geophys. Res., Vol. 104, No. B6, page 13, Figure 2; © 1999, by permission of American Geophysical Union).

Map showing the epicenter of the Colombia earthquake (red star) determined by using a network of globally distributed stations (blue triangles). For comparison we plotted the epicenter from the single station (BFO, see label) 3-component location as a green star. For details of the BFO location see the next section.

## 6 Single station 3-component source location

So far we have demonstrated how data from a global network can be processed in SEISAN. This is nowadays the common procedure as the data from a large number of stations are now freely accessible via Internet. However, it is also possible with SEISAN to estimate the event location by analyzing only the three-component records of a single station. The epicentral distance of the station can be determined best from the time difference S-P, but also using time differences of P to other later phases such as PP, SP or even SS (see Fig. 11.23 of Chapter 11 in Bormann2009, and EX 11.2). SKS-P is not suitable, because this time difference does not change much with distance. The backazimuth can be determined from the amplitude ratios of the three components (see Figure 1 and text in IS 11.1 and EX 11.2). For the backazimuth calculation the method of Roberts et al. (1989) is implemented in SEISAN.

We start with the determination of the back-azimuth from the P-wave first-motion amplitudes, as we need the backazimuth to rotate the seismograms into the ZRT system, which we will use to identify the phases.

*Three-component analysis of station BFO at  $\Delta = 86.4^\circ$ , filtered 0.01-0.1 Hz:* From the above trace plot we see a positive correlation between the vertical and the two horizontal components. By definition this means that first motion direction of P in the horizontal components shows toward the source, which is in the south-west. However, since the N-S amplitude is much smaller than the E-W amplitude (compare the numbers on the outermost right side of the traces), we can further conclude that the ray is coming more from the west than from the south thus matching for station BFO a backazimuth of  $262^\circ$ .

In the next step we estimate the epicentral distance via the time difference between P and identified later arriving phases.

*Three-component analysis of station BFO at  $\Delta = 86.4^\circ$ , unfiltered:* From the time difference between P with PP and S (here identified as SKS on the middle trace and as the slightly later arriving S on the bottom trace) we estimate the epicentral distance, assuming a source depth of 150 km according to the pP-P time (see Table below). This depth estimate agrees reasonably well with interpreting the strong onsets that follow SKS. S arrives about 13 s after SKS and the depth phase sS 74 s after S, corresponding at  $\Delta = 86.4^\circ$  to a computed source depth of 170 km according to the IASP91 tables. This gives some feeling for the possible influence of errors in the assumed velocity model, phase interpretation and/or onset-time piking on the estimation of source depth.

We can either read the distance for which we get the best match between our observations and the travel time curves of the global IASP91 velocity model, or equivalently estimate it with a grid search by computing travel times for a range of distances as done here. In our example we then get  $\Delta = 86.5^\circ$  (see Table below). This differs only  $0.15^\circ$  from our first multi-station P-wave location ( $86.35^\circ$ ) and even less from our improved multi-station and multi-phase location ( $86.56^\circ$ ) (see above location program outputs). Together with the backazimuth we can now locate the event on a suitable stereographic map with station BFO in the center (as in Figure 12 of EX 11.2 for an Ecuador earthquake and station CLL).

| Phase difference | Time difference $\delta t(s)$ | $\delta t(s)$ for $\Delta = 86^\circ$ | $\delta t(s)$ for $\Delta = 87^\circ$ |
|------------------|-------------------------------|---------------------------------------|---------------------------------------|

*Output from the location program:* We can obtain a single-station three-component location, which is within 500 km from the one obtained by the standard location program with several stations. While our distance estimate is very good, we would have to get a 5° larger back-azimuth reading to get a location very close to the multi-station location. This shows the approximate range of uncertainty of single station locations in the far teleseismic range. Wrong phase interpretation may increase single station location errors. E.g., when interpreting in this case the earlier arriving SKS as S, the distance estimate from S-P would be 0.2° shorter in the case of BFO but this underestimation would increase for any station further away within the distance range where SKS arrives before S (see differential travel-time curve in Figure 4 of EX 11.2). For shallow earthquakes at  $\Delta = 100^\circ$  the error  $\delta\Delta$  would reach already 0.9°. However, with proper S-P times, or when several other phases have also been correctly identified, the distance can generally be estimated, up to 160°, within 1-2° and the azimuth with P-wave first motion amplitudes, when measured with good signal-to-noise ratio on well calibrated 3-component seismometer components, within about 5-10°. This allows rather fast and reasonably good first location estimates even with single station data only (see Fig. 11.23 in Chapter 11 of NMSOP-1 in Bormann, 2009, and examples in EX 11.2).

Finally, we determine the teleseismic magnitudes for this earthquake. Since this is a deep earthquake, only the two teleseismic standard body-wave magnitudes  $m_b$  and  $mB\_BB$  should be calculated. Note, however, that the IASPEI WG on magnitudes encourages stations to measure according to the standard procedures also IAMs\_20 and IVMs\_BB with their periods if surface-waves are still clearly visible in records of deeper earthquakes as this is the case also for our example (see, e.g., in section 5, the record trace for station KADAK in the plot: *Vertical-component traces for which phases are picked, filtered 0.02-5 Hz*). Such data are of great interest for investigating the depth and period dependence of surface waves and to derive improved calibration functions  $\sigma(\Delta, h, T)$ . Note that for 20 s surface-waves and thus  $M_s$ \_20 calculation such depth corrections have already been published by Herak et al. (2001):

$$\begin{aligned}
 \Delta M_s(h) &= 0 & \text{for } h < 20 \text{ km} \\
 \Delta M_s(h) &= 0.314 \log(h) - 0.409 & \text{for } 20 \text{ km} \leq h < 60 \text{ km} \\
 \Delta M_s(h) &= 1.351 \log(h) - 2.253 & \text{for } 60 \text{ km} \leq h < 100 \text{ km} \\
 \Delta M_s(h) &= 0.400 \log(h) - 0.350 & \text{for } 100 \text{ km} \leq h < 600 \text{ km.}
 \end{aligned}$$

For station KDAK, e.g., one would measure IAMs\_20 = 10078 nm at  $T = 19$  s and thus get a depth corrected  $M_s$ \_20 = 6.2 + 0.5 = 6.7 which compares rather well with our body-wave magnitudes  $m_b = 6.8$  and  $mB\_BB = 7.0$  determined in the following.

*Amplitude reading for mb magnitude at station CMLA at  $\Delta = 59.9^\circ$ :* As in the case of the regional event, the upper broadband trace is converted into a WWSSN short period trace (lower trace) on which the amplitude Iamb is read, here as 1148 nm with a period of 2.3 s.

*Amplitude reading for mB\_BB magnitude at station CMLA at  $\Delta = 59.9^\circ$ :* As in the case of the regional event the amplitude IVmB\_BB is read on the bottom trace that has been deconvolved into a broadband velocity trace (top trace shows uncorrected data, which are in the case of a broadband seismometer also proportional to velocity): here 36758 nm/s with a period of 2.5 s.

Computing the average magnitudes from all station amplitude observations we get the values below. In this case mB\_BB is equal to Mw, and mb is only slightly smaller. Since the period at which mb is read is almost the same as for mB\_BB the difference is mainly due to the larger bandwidth of the broadband record.

| Magnitude scale | Value |
|-----------------|-------|
| Mw (USGS)       | 7.0   |
| mb              | 6.8   |
| mB_BB           | 7.0   |

The following station amplitude readings were used in the event magnitude computation:

|      |    |       |         |      |         |    |     |      |     |
|------|----|-------|---------|------|---------|----|-----|------|-----|
| EFI  | BZ | dist: | 6121.0  | amp: | 13012.5 | T: | 2.7 | mB = | 6.9 |
| EFI  | BZ | dist: | 6121.0  | amp: | 788.3   | T: | 1.1 | mb = | 6.5 |

## 7 Concluding remarks

The examples given here are meant to illustrate how the data processing is done using the SEISAN software and to illustrate some basic concepts of earthquake data processing. The examples should help newcomers to earthquake data processing to get started. It will be necessary to first learn SEISAN, but then the data used can be downloaded and the steps shown here followed. When analyzing seismograms, the number of phases that can be read depends on the earthquake size and thus the SNR of the recording, the epicentral distance, the source depth as well as on the bandwidth and period range of the seismic records (see Figs. 2.57-2.61 in Chapter 2). From a scientific perspective we wish to have as many good phases read as possible. However, there is often a limitation of how much can be done due to time constraints. We encourage the reader to read more than the first arriving P, and at least to identify clear additional later phases. A good exercise is to download data from the IRIS Wilber, take the data into SEISAN and start processing.

## Acknowledgments

Our thanks go to Jens Havskov, Won-Young Kim and James Dewey. Their review comments helped to improve this manuscript.

## User Manual for HYPOSAT (including HYPOMOD)

### 1 Introduction

**HYPOSAT** is a program package developed to locate seismic sources. It utilizes travel-time data, backazimuth (*i.e.*, station-to-event azimuth) values, and ray-parameter values. Phases considered are those included in IASP91-type tables, and reflections from the Conrad and from the Mohorovičić discontinuities, if local models are used. The program follows the phase name recommendations of the IASPEI Working Group on Standard Phase Names (see IS 2.1). Additionally, all possible travel-time differences between different onsets at individual stations are estimated and can be included in the location process (*e.g.*, PcP-P as an additional constraint for the source depth). If amplitude and period measurements for P onsets or surface waves are available, station magnitudes and an event magnitude can also be estimated. More details about the general features of the program can be found in Schweitzer (1997, 2001a).

The data files containing the global models (*e.g.*, **iasp91.tbl** and **iasp91.hed**), the list of up to now defined seismo-tectonic units (**REG\_L3.DAT**), the attenuation curves for magnitude estimations (**MB\_G-R.DAT** and **MB\_V-C.DAT**), and the ellipticity corrections (**elcordir.tbl**) must all be located in the same directory. The path to this directory must be set by the environment variable **HYPOSAT\_DATA**.

The program needs two input files in ASCII format. One file contains the general parameters to steer the inversion process (**hyposat-parameter**) and the other file contains the observed data for the event to be localized (**hyposat-in**). Contents and structure of these files will be explained in the following sections.

The program **HYPOMOD** uses the same input files as **HYPOSAT** but it only calculates all residuals for a given hypocenter without any inversion.

The newest versions of the programs **hyposat\_hypomod** (including source code, this manual, the PDF version of Schweitzer (1997), data files containing travel-time models and station parameters, and several examples) are located in six compressed tar-files (all versions in **hyposat.version.tar.Z** or **hyposat.version.tar.gz**, the UNIX version in **hyposat\_u.version.tar.Z** or **hyposat\_u.version.tar.gz**, and the LINUX version in **hyposat\_l.version.tar.Z** or **hyposat\_l.version.tar.gz**) for free download either directly from the program list in the NMSOP-2 cover page folder *Download Programs & Files* or from NOR SAR's anonymous ftp-address <ftp://ftp.norsar.no> under the directory `/pub/outgoing/johannes/` *hyposat*. The address when using your web-browser is: <http://ftp.norsar.no/pub/outgoing/johannes/hyposat>.

Questions related to program updates and maintenance should be directed to the author.

## 2 Getting started

This section describes how some simple examples for **HYPOSAT** can be started and executed. The simplest way to use the program for own locations is to start from one of the following examples and modify input data and parameters for your needs. The meaning and format of the input is described in the following sections.

### Installation of **HYPOSAT**:

1) Make a sub-directory for **HYPOSAT**, copy the compressed tar-file containing the *hyposat-software package* from the NORSAR's ftp site (*ftp.norsar.no*), decompress it, and run:

```
tar -xvf hyposat.version.tar or
tar -xvf hyposat_u.version.tar or
tar -xvf hyposat_l.version.tar,
depending on the module you have downloaded.
```

Then you will have a directory containing the following files and subdirectories in the UNIX Solaris) case:

```
bin/    data/    examples/ man/  README_u  src/
```

or in the LINUX:

```
bin_l/  data_l/  examples_l/ man/  README_l  src_l/
```

or all together if you had downloaded the full version.

The file *README\_u* (or *README\_l*) contains a complete list of all files following with the installed *hyposat-software package* and a explanation of these files.

2) If needed re-compile the software in the */src* (or */src\_l*) subdirectory by running:  
*make* and/or *make -f Makefile.hypomod*

### Executing **HYPOSAT**:

Change to the subdirectory *examples/* (or *examples\_l*).

Here you will find input file examples for four different cases: an event observed with a network of stations (*.net*), a single array (*.single\_array*), a set of local and regional stations (*.regional*), and a teleseismically observed event (*.tele*). **HYPOSAT** runs with two input files. To check your installation, try the following:

```
cp hyposat-in.net hyposat-in
cp hyposat-parameter.net hyposat-parameter
setenv HYPOSAT_DATA $path/hyposat/data
(or setenv HYPOSAT_DATA $path/hyposat/data_l)
(where $path is the actual path to the subdirectory hyposat)
and run:
```

```
../bin/hyposat (or ../bin_l/hyposat)
```

You will then get an output file *hyposat-out*, which should be identical to the file *hyposat-out.net* distributed with the *hyposat-software package*.

### 3 The File *hyposat-parameter*

The file containing the inversion-steering parameters must (!) have the name *hyposat-parameter* and must reside in the actual directory where the program is executed. The structure and contents of *hyposat-parameter* is as follows:

-----start of the example for a *hyposat-parameter* file -----

hyposat-parameter file for hyposat 4.4

-----end of the example-----

The order in which these parameters are set is arbitrary. The parameters must be identified with the above given description (bold-faced). The parameters must be written in the file in capital letters! The settings itself must follow after the 37th character of the line (*i.e.*, in this example two characters after the colon). Whenever a line does not comply with this rule, it will be ignored (*e.g.*, blank lines or lines starting with a '\*', ...). This file is read only once at the beginning of a location run. Each line can be repeated several times within the file with another setting. In this case, the last set value is used for the location process. For file names, the full path name can be given. In the following all the parameters are explained in more detail:

**GLOBAL MODEL:** Type of the reference model used to calculate all travel time related theoretical data. This package contains the following models:

|        |                                                           |
|--------|-----------------------------------------------------------|
| ak135  | AK135 model (Kennett <i>et al.</i> , 1995)                |
| iasp91 | IASP91 model (Kennett, 1991; Kennett & Engdahl, 1991)     |
| jb     | Jeffreys-Bullen model (Jeffreys & Bullen, 1940 and later) |
| prem   | PREM model (Dziewonski & Anderson, 1981)                  |
| sp6    | SP6 model (Morelli & Dziewonski, 1993)                    |

The directory where these travel-time tables reside must be specified with the environment variable **HYPOSAT\_DATA** before the program is started. The travel-time tables are based on the **libtau**-software package written by Ray Buland and distributed as IASP91-software. If you use an own version of the **libtau**-software, you will have to exchange the **libtau\_h.f** file (see **Makefile** in the source-code directory) and to exchange the corresponding data files (**\*.hed** and **\*.tbl**) because for the version included here some parameter and dimension settings were changed in the include file **ttlim.h**.

**GLOBAL MODEL 2:** Here one can give the name of any other second global model to be used for specific ray paths indicated in the data input file.

**GLOBAL MODEL 3:** Here one can give the name of any other third global model to be used for specific ray paths indicated in the data input file.

**GLOBAL MODEL 4:** Here one can give the name of any other fourth global model to be used for specific ray paths indicated in the data input file.

**LOCAL OR REGIONAL MODEL:** Name of the file with a local (or regional) velocity model. Travel times will be estimated for the following seismic phases (as far as they can be observed with respect to distance and source depth): Pg, Pb, Pn, P, pPg, pPb, pPn, pP,

PbP (i.e., in this program upper side reflection from the 'Conrad'), PmP, PgPg, PbPb, PnPn, PP, and the converted phases sPg, sPb, sPn, sP, SbP and SmP. The same phase set is used for S-type phases, respectively.

This parameter (file name) must only be set if a special local or regional model is to be used instead of the global one. The velocity model must contain the following information:

In the first line maxdis = maximum distance in [deg] for which this model shall be used. It is followed by the depth in [km], the P-phase velocity  $V_p$  in [km/s], and the S-phase velocity  $V_s$  in [km/s]. The model may contain layers with a constant velocity or with velocity gradients. First order discontinuities must be specified with two lines for the same depth. Additionally, the Conrad- and the Mohorovičić-discontinuities should be marked as shown in the following example. Otherwise, all calculated phases would be called Pg (or Sg).

```
-----example for a file containing a regional velocity-----
10.      | maxdis in free format
      0.000      5.400      3.100      | depth, vp, vs in format (3F10.3)
      10.000     5.800      3.200
      20.000     5.800      3.200CONR      | + mark for the 'Conrad'
      20.000     6.500      3.600      | in format (3F10.3,A4)
      30.000     6.800      3.900MOHO      | + mark for the 'Moho'
      30.000     8.100      4.500
      77.500     8.050      4.400
      120.000    8.100      4.500
-----end of example-----
```

**PHASE INDEX FOR LOCAL MODEL:** This parameter allows the user to specify the set of seismic phases, for which travel times and their partial derivatives will be calculated in the local/regional model:

The parameter is a 4 digit number. The position of a digit defines the phase type for which the value of the digit defines the action for this phase:

dxxx the digit (d) at this place is the flag for surface reflections (e.g., pP or sS)

xidx the digit (d) at this place is the flag for surface multiples (e.g., PP or SS)

xxdx the digit (d) at this place is the flag for reflections at the Conrad- or the Mohorovičić-discontinuity (e.g., PbP or SmS). Note that the here used name 'PbP', to indicate reflection from the Conrad discontinuity, is not a regular phase name as recommended by the IASPEI Working Group on Standard Phase Names (see IS 2.1).

xxxd the digit (d) at this place is the flag for converted phases (e.g., sP or PmS)

d itself can have the following values:

d = 1 only P-type onsets will be calculated

d = 2 only S-type onsets will be calculated

d = 3 both phase types (P and S) will be calculated

e.g.,: 1320 means: the phases pP, PP, SS, SbS and SmS will be calculated but no conversions. 000 or simply 0 means: none of these phases will be calculated.

The direct phases Pg, Pb, Pn, P (or the same for S) will always be calculated as long as the **PHASE INDEX FOR LOCAL MODEL** is not set to a negative value.

**CRUST 5.1 PATH:** The path to the directory where the CRUST 5.1 data files (Mooney *et al.*, 1998) reside.

**CRUST 5.1:** This parameter controls the usage of the model CRUST 5.1:

= 0 CRUST 5.1 is not used at all.

= 1 CRUST 5.1 is used to calculate station corrections with respect to the local crustal structure below the station.

- = 2 CRUST 5.1 is used to define a local/regional velocity model between the source and stations up to a distance of 6 deg.
- = 3 CRUST 5.1 is used to define a local/regional velocity and to correct for local crustal structures at the stations and at reflection points at the Earth's surface. If this parameter is set to any value larger than 0 and the model CRUST 5.1 is available, a time correction for the crustal structure at the reflection point of phases reflected at the Earth's surface will be calculated (*e.g.*, PnPn, sS, P'P', ...)

**OUTPUT OF REGIONAL MODEL:** This flag defines if the local/regional model used for the final inversion is to be printed out in the output file (**hyposat-out**). This option is particularly interesting whenever this velocity model was interpolated from CRUST 5.1:

- 0 no model output (default)
- 1 model output

**STATION FILE:** Name of the file with station coordinates either in NEIC or in CSS 3.0 file format. Only these two formats are currently supported! To get the location results faster, the usage of a file containing only your usually used stations is recommended.

**STATION CORRECTION FILE:** Name of the file for station corrections. This file must contain the station name and then the local velocities for P and S waves below this station to calculate the best elevation correction for this station. This value can also be used to correct for a known velocity anomaly below this station. The input is format free. If such information is not available, leave it blank. If one station is not in this list, the default values as defined by the input parameters **P-VELOCITY TO CORRECT ELEVATION** and **S-VELOCITY TO CORRECT ELEVATION** are used!

-----example for a file containing station corrections -----  
 GEC2 5.2 3.2 | in free format  
 -----end of example-----

**P-VELOCITY TO CORRECT ELEVATION:** Local P velocity ( $V_{pl}$ ) to correct for the station elevation (default 5.8 km/s) if this parameter is not set in the **STATION CORRECTION FILE**. If  $V_{pl} = 99$ , a station-elevation correction is not applied and the **STATION CORRECTION FILE** is not used.

**S-VELOCITY TO CORRECT ELEVATION:** Local S velocity ( $V_{sl}$ ) to correct for the station elevation (default  $V_{pl}/\sqrt{3}$ ), if not given in **STATION CORRECTION FILE**.

**LG GROUP-VELOCITY:** A group velocity for Lg can be defined; the default value is 3.5 [km/s].

**RG GROUP-VELOCITY:** A group velocity for Rg can be defined; the default value is 2.5 [km/s].

**LQ GROUP-VELOCITY:** A global group velocity for Love wave. (LQ) can be defined; the default value is 4.4 [km/s].

**LR GROUP-VELOCITY:** A global group velocity for Rayleigh waves (LR) can be defined; the default value is 3.95 [km/s].

**STARTING SOURCE LATITUDE:** Initial value for event latitude (no default value, an initial latitude will be estimated or chosen from the input data). Valid range: -90 deg ≤ value ≤ 90 deg. An initial solution must be set for both latitude and longitude!

**STARTING LATITUDE ERROR:** Its standard deviation (default 10 deg).

**STARTING SOURCE LONGITUDE:** Initial value for event longitude (no default value, a start longitude will be estimated or chosen from the given data). Valid range: -180 deg ≤ value ≤ 180 deg. An initial solution must be set for both latitude and longitude!

**STARTING LONGITUDE ERROR:** Its standard deviation (default 10 deg).

**STARTING SOURCE DEPTH:** Starting value for the event depth (default 0. km).

**STARTING DEPTH ERROR:** Its standard deviation (default 50 km).

**DEPTH FLAG:** Flag to handle the source depth:

f or F the hypocenters depth is fixed for this inversion, as defined by **STARTING SOURCE DEPTH**.

d or D the depth will be inverted from the beginning.

b or B means both: *i.e.*, the inversion begins with the fixed depth from **STARTING SOURCE DEPTH** and after reaching a stable solution, the routine also tries to invert for the source depth. Both solutions (fixed and free depth) will be listed in *hyposat-out* (see example).

**STARTING SOURCE TIME:** Initial value for source time in epochal time format. The initial source time can be given in three different formats: as epochal time (*i.e.*, the number of seconds after 01 January 1970 00:00:00), and in two human readable formats yyyy-doy:hh.mm.ss.sss (DOY = day-of-year) and yyyy-mo-dd:hh.mm.ss.sss. For example, the 1 October 2002 at 3 o'clock in the afternoon can be written as 1033484400.0 (epochal time) or as 2002-274:15.00.00.000 or as 2002-10-01:15.00.00.000.

If this value is not set, an initial source time will be estimated from travel-time differences between direct S type and direct P type observations by using Wadati's approach. For this, the program calculates a Vp/Vs relation for each phase type and estimate a source time, respectively. The initial source time is then the mean value of all estimated source times. In the case of only one S-P observation, Vp/Vs is set to sqrt(3.). If no S-P time observation is available, the source time is set to the earliest observed onset time.

**STARTING TIME ERROR:** its standard deviation (default 120 s).

**MAXIMUM # OF ITERATIONS:** To avoid indefinite iterations to find a solution, a maximum number of iterations must be defined (default 80).

**# TO SEARCH OSCILLATION:** Here the number of solutions from older iterations can be defined with which the newest solution will be compared to identify iterations between very similar solutions (oscillating solutions). The default value is 4 and the maximum number is 10.

**LOCATION ACCURACY:** If we calculate the distance between the solutions of two consecutive iterations in km, this value gives the maximum vector length to stop the iteration process. The default value is 1 km (also if **LOCATION ACCURACY** is set to 0.).

**CONSTRAIN SOLUTION:** If this flag is set to 1 (default value), all used observations are checked for their residuals and only the data with relatively small residuals are used for a final inversion.

0 no final restriction of data

1 final restriction of data (default).

**CONFIDENCE LEVEL:** Level of confidence for the output of uncertainties in percent, the default uncertainty is +/- one standard deviation (*i.e.*, ca. 68.3%).

**EPICENTER ERROR ELLIPSE:** The setting of this flag defines whether an error ellipse for the final solution will be calculated or not. The size of the error ellipse corresponds to the chosen confidence level.

0 no error ellipses

1 error ellipses will be calculated (default).

**SLOWNESS [S/DEG]:** The slowness of a seismic phase can be given as input value in two different units: apparent velocity or ray parameter. All slowness values must have the same unit in the data input file *hyposat-in*:

0 the slowness input values are apparent velocities in [km/s]

- 1 the slowness input values are ray parameters in [s/deg]
- MAXIMUM AZIMUTH ERROR:** Maximum value of a backazimuth-residual to use this observation as a defining phase in [deg].
- MAXIMUM SLOWNESS ERROR:** Maximum value of a slowness-residual to use this observation as a defining phase in [s/deg].
- FLAG USING TRAVEL-TIME DIFFERENCES:** By default, the program uses the travel-time differences between all phases observed at one station to estimate a hypocenter. This can be switched off:
- 0 travel-time differences are not used
- 1 travel-time differences are used (default)
- MAGNITUDE CALCULATION:** Flag if body wave (mb) or surface wave (Ms) magnitudes are calculated for this event.
- 0 magnitudes are not calculated (default)
- 1 magnitudes are calculated
- P-ATTENUATION MODEL:** With this parameter the attenuation model used for mb calculations can be chosen. The two possibilities are **G-R** for Gutenberg-Richter (Gutenberg and Richter, 1956a, b) or **V-C** for Veith-Clawson (Veith and Clawson, 1972). No default model is defined!
- S-ATTENUATION MODEL:** With this parameter the attenuation model used for Ms calculations can be chosen. The two possibilities are **IASPEI** for the IASPEI 1967 formula (often also called Praha formula) or **R-P** for the Rezapour and Pearce (1998) formula. No default model is defined!
- INPUT FILE NAME:** A file name can be defined at this place if not the standard input-file name (*hyposat-in*) should be used.
- OUTPUT SWITCH:** This flag determines whether any output file (see also **OUTPUT FILE NAME**) will be written:
- 0 no output file
- 1 output file will be written (default)
- OUTPUT FILE NAME:** A file name can be given at this place if not the standard output-file name (*hyposat-out*) should be used.
- OUTPUT LEVEL:** Verbosity level for output during the location process on screen (0 – 10) or on file (>10) during the inversion; the default value is 4. If **OUTPUT LEVEL** > 10, the output level for the screen is internally calculated. In addition, the resolution, covariance, correlation, and the information-density matrix will then be written out in a file called *hyposat-gmi.out*. This file contains always the named matrices for the last inversion. **OUTPUT LEVEL** can be set to the following values:

| Input   | Matrix Output                                                                     | Screen Output Level |
|---------|-----------------------------------------------------------------------------------|---------------------|
| 0 – 10  | None                                                                              | 0 – 10              |
| 11      | the resolution matrix will be written out.                                        | 0                   |
| 12      | the covariance matrix will be written out.                                        | 1                   |
| 13      | the correlation matrix will be written out.                                       | 3                   |
| 14      | all three matrices will be written out.                                           | 5                   |
| 15      | "                                                                                 | 7                   |
| 16      | "                                                                                 | 9                   |
| 17 – 19 | "                                                                                 | 10                  |
| 20      | ", plus the diagonal elements of information -density matrix will be written out. | 0                   |
| 21 – 29 | "                                                                                 | as for 11 – 19      |
| 30      | ", plus the whole information-density matrix                                      | 0                   |

|         |                      |                |
|---------|----------------------|----------------|
|         | will be written out. |                |
| 31 – 39 | "                    | as for 11 – 19 |

## 4 The File *hyposat-in*

**HYPOSAT** then needs a file with all the readings for a specific event: This file has by default the name *hyposat-in* but the name can be defined in the parameter file *hyposat-parameter*. The data-input file must have the following format:

1. line: any title for event identification of maximum 80 characters (used also in the output-file *hyposat-out*).
2. – (n+1)'th line with the n-observed onsets. This line must (!) be compatible with the following format (FORTRAN):

If we don't wish to calculate magnitudes (see **MAGNITUDE CALCULATION** in the *hyposat-parameter* file) this line can contain the following data with the following format:

```
(a5,1x,a8,1x,i4,4(1x,i2),1x,f6.3,1x,f5.3,1x,f6.2,3(1x,f5.2),1x,a6)
```

station name, phase name, year, month, day, hour, minute, second, standard deviation of the onset time, backazimuth, standard deviation of the backazimuth observation, either ray parameter [s/deg] or apparent velocity [km/s] (see **SLOWNESS [S/DEG]** in the *hyposat-parameter* file), standard deviation of the slowness observation in [s/deg] or [km/s], and a six character long combination of controlling flags. These steering flags (**123456**) have the following meanings and options:

- Position **1** the time reading of this onset can be used ('T' or 't') or not used ('\_') for the inversion.
- Position **2** the backazimuth reading of this onset can be used ('A' or 'a') or not used ('\_') for the inversion.
- Position **3** the slowness reading of this onset can be used ('S' or 's') or not used ('\_') for the inversion.
- Position **4** the time reading of this onset can be used ('D' or 'd') or not used ('\_') to calculate travel-time differences and use them in the inversion.
- Position **5** the onset-time reading of this onset will be corrected ('R' or 'r') or not corrected ('\_') for the crustal structure below a reflection point at the Earth's surface by calculating the travel-time difference for the crustal path between the used global model (as set with **GLOBAL MODEL** in *hyposat-parameter*) and CRUST 5.1.
- Position **6** if set to '2', '3', or '4', the other global Earth model (as set with **GLOBAL MODEL 2**, **GLOBAL MODEL 3**, or **GLOBAL MODEL 4** in *hyposat-parameter*) will be used to calculate the theoretical onset time, the ray parameter, and their partial derivatives for this onset. With any other character at this place the standard global Earth model (see **GLOBAL MODEL** in *hyposat-parameter*) will be used.

Keeping all positions 1 – 6 blank, the flag combination **TASDR\_** will be used as default value.

If one also wishes to calculate magnitudes (see **MAGNITUDE CALCULATION** in *hyposat-parameter*) this line can contain the following data in the following format:

(a5,1x,a8,1x,i4,4(1x,i2),1x,f6.3,1x,f5.3,1x,f6.2,3(1x,f5.2),1x,a6,1x,f6.3,1x,f12.2)

station name, phase name, year, month, day, hour, minute, second, standard deviation of the onset time, backazimuth, standard deviation of the backazimuth observation, either ray parameter [s/deg] or apparent velocity [km/s] (see **SLOWNESS [S/DEG]** in the *hyposat-parameter* file), standard deviation of the slowness observation in [s/deg] or [km/s], the six character long combination of controlling flags (see above), the period of the observed onset, and finally the amplitude of the signal in [nm].

S-type onsets must always be listed after the corresponding P-type onsets – if not, the travel-time difference between these two onsets (S-P) cannot be used for calculating a starting solution for source time and distance from the corresponding station. If it is unknown, of which type the P or S onsets are, you can choose the names P1 or S1 to tell the program that you know it is the first P or the first S onset at this station. Then the program itself chooses the right phase name depending on the distance of the observation.

Onsets with a station name starting with a \* and lines starting with a blank character are not used.

The values for backazimuth, slowness, period, and amplitude are optional. If backazimuth or slowness values are not available, they must be set to -999. or -1.; the amplitude/period information is only used if both values are larger than 0.

For each phase name not defined by the applied travel-time model(s), the program searches for the best fitting phase. However, onset time and ray parameter of such a phase are not used in the inversion, but eventually the backazimuth information!

When using the correct format, an input file can look like the following example:

```

## 5 The File hyposat-out

With the above example for a *hyposat-in* file you will get the following output-file *hyposat-out*: This example was calculated on a UNIX system, the results on a LINUX system might be slightly different. Explanations are included in [ .... ]:

-----example for a *hyposat-out* file -----

HYPOSAT Version 4.4

NORTHERN MOLUCCA SEA, 1996 29 June, from pIDC's Reviewed Event Bulletin (REB)

Parameters of starting solution ( 1 standard deviation):

[ Not all backazimuth-observation pairs are used: if one station is more than 170 deg apart from the crossing point, this crossing point is skipped. ]  
 Mean epicenter calculated from 165 backazimuth observation pairs  
 Mean epicenter lat: 29.4748 42.0082 [deg]  
 Mean epicenter lon: 121.5921 6.0977 [deg]

[ type 1: S - P or S1 - P1 observation, type 2: Sg - Pg observation, type 3: Sn - Pn observation, type 4: Sb - Pb observation ]  
 S-P Travel-time difference type 1 with 2 observation(s)  
 Mean source time: 836008582.700 11.636 [s]  
 Mean vp/vs: 1.758 0.035

Iterations : 7  
 Number of defining: 58  
 First reference model : ak135  
 Second reference model : iasp91

The new source parameters

Confidence level of given uncertainties: 68.27 %

Source time : 1996 06 29 00 36 42.801 0.150 [s]  
 or 836008602.801 0.150 [s]  
 Epicenter lat: 1.3045 0.0250 [deg]  
 Epicenter lon: 126.3165 0.0611 [deg]  
 Source depth : 0.00 [km] Fixed

Epicenter error ellipse:  
 Major axes: 5.98 [km] Minor axes: 3.61 [km]  
 Azimuth: 62.0 [deg] Area: 67.82 [km\*2]

Flinn-Engdahl Region ( 266 ): Northern Molucca Sea

Magnitudes: 4.39 (mb, G-R) 3.57 (Ms, R-P)

|-------------------------|-------|---------|-------|------|--------|--------|------|-------|-------|-----|-------|
| 1996-06-29 00 36 49.169 | 1.321 | 126.297 | 44.50 | 1.76 | 0.0147 | 0.0348 | 4.28 | 0.478 | 0.04  | 58  | 0.658 |

-----end of the example-----

## 6 The Program HYPOMOD and the File hypomod-out

For a given seismic hypocenter solution, the program **HYPOMOD** calculates the residuals for all observed data: the travel times, the backazimuths, and slowness values. With the example given here for a hypocenter inversion with **HYPOSAT**, one has only to modify slightly the *hyposat-parameter* file and then one can apply the program **HYPOMOD**. The modifications needed in *hyposat-parameter* are to set for the starting source parameters the inversion results. Then you will get an output-file called *hypomod-out*, which has in principle the same format as *hyposat-out*.

--- example for changes in *hyposat-parameter* -----

**STARTING SOURCE LATITUDE [deg] : 1.3211**

**STARTING SOURCE LONGITUDE [deg] : 126.2965**

**STARTING SOURCE DEPTH [km] : 44.50**

**STARTING SOURCE TIME (epochal time): 836008609.169**

or

**STARTING SOURCE TIME (DOY) : 1996-181:00.36.49.169**

or

**STARTING SOURCE TIME (HUMAN) : 1996-06-29:00.36.49.169**

Then run **HYPOMOD** and you will get an output file *hypomod-out* which will look like:

-----example for a *hypomod-out* file -----

HYPOMOD Version 1.1

NORTHERN MOLUCCA SEA, 1996 29 June, from pIDC's Reviewed Event Bulletin (REB)

The source parameters

Source time : 1996 06 29 00 36 49.169  
 or 836008609.169  
 Epicenter lat: 1.3211 [deg]  
 Epicenter lon: 126.2965 [deg]  
 Source depth : 44.50 [km]

## User Manual for LAUFZE and LAUFPS

### 1 Introduction

The program **LAUFZE** calculates travel-time curves for a P- or an S-velocity model. This is a newer version of a routine, which was originally developed in the 1970s at the Institute of Geophysics in Karlsruhe, Germany, by the late Prof. Gerhard Müller and Dr. Christoph Gelbke. Since then, the author has extended the code to include many new features and options, in particular for calculating different types of teleseismic and of multiply reflected or refracted phases. These changes were made at the Institute for Meteorology and Geophysics, University of Frankfurt, Germany, the Institute of Geophysics, Ruhr-University Bochum, Germany, and, most recently, at NORSAR.

The travel-time curves can be calculated for horizontally layered or spherically symmetric models with or without reduced time scale. The velocity model is defined by input as a function of the depth  $z$ , the dominant signal period  $T_{sig}$ , and the depth-dependent quality factor  $Q$  given for a reference period  $T_{ref}$ . Then, with this as input information, the program calculates and then uses the **group velocity** for the different model depths as defined by:

$$u(z, T, Q) = v(z) \cdot \left(1 + \frac{1}{\pi \cdot Q(z)} \cdot \left(\ln\left(\frac{T_{ref}}{T_{sig}}\right) + 1\right)\right)$$

If no  $Q$ -structure is given, the program uses as default value  $Q(z) = 10^6$ . However,  $Q$  is always assumed to be frequency independent.

The source can be placed in any depth as well as the ‘receivers’. However, the ‘receivers’ are by default assumed to be at the Earth’s surface. In the case of a spherical Earth model the Earth radius used for the Earth-flattening transformation is 6371 km. However, the Earth’s centre cannot be reached! The velocities for depths, at which they are not explicitly given, are linearly interpolated.

The whole program is based on the ray approximation of seismic waves, which means that the different kinds of seismic phases must be separately defined by the input parameters. Travel-time curves for the following phase types can be calculated:

- I Direct waves from the source to the Earth’s surface (only in the case that the source is not at the surface).
- II Diving waves from the source radiated down in the Earth.

- III Reflections from any layer below the source, back to the Earth's surface (*e.g.*, PcP, ScP, PmP).
- IV Reflections of diving waves at any layer back down into the Earth (*e.g.*, PP, SS, PKKP, SKKS).
- V Multiple [reflections](#) between any two layers (*e.g.*, PPmP, a diving P wave from [the](#) source to the Earth's surface, reflected from there back into the Earth, and finally reflected at the Mohorovičić (Moho) discontinuity back to the surface).
- VI For the phases III – V, any number of multiple reflections can be calculated (*e.g.*, P3, P5KP, SmS3).
- VII If the source is not at the surface, for all phases of II – VI the corresponding surface reflections can be calculated (*e.g.*, pP, sScS, pP3KP).
- VIII The multiple reflection(s) as defined under V will automatically be calculated for all above defined phases. That means, *e.g.*, not only for the direct P phase a Moho reverberation PPmP will be calculated but also *e.g.*, for pPKP we will get a pPKPPmP phase.
- IX For the direct to the surface radiated wave (see I) reflections can be calculated from any layer between source and the Earth's surface down back into the Earth (*e.g.*, p450P, or smS, but also pP).

All parameters for steering the program must be given in a formatted ASCII file. The program asks for the name of the input file.

All results of the program are written in a ASCII file called **laufze-out**. This file can then easily be edited and the listed travel-time curves can then be plotted with any plotting routine or used as ASCII input for other programs.

**LAUFPS** is a program like **LAUFZE** but it calculates travel times not only for one model (P or S) but also for both models together in one step, including converted phases. However, this program cannot be used to place 'receivers' below the Earth's surface. All settings for **RECE** (see below) are ignored!

The newest versions of the programs **laufze\_laufps** (including source code, this manual, data files containing examples for input and output files) are located in two compressed tar-files; either in **laufze.version.tar.Z** or in **laufze.version.tar.gz**. They can be downloaded for free either directly from the program list in the NMSOP-2 cover page folder *Download Programs & Files* or from NORSAR's anonymous ftp-server [ftp.norsar.no](ftp://ftp.norsar.no) under the directory */pub/outgoing/johannes/lauf*. If using your web-browser, the address is: <ftp://ftp.norsar.no/pub/outgoing/johannes/lauf>. Questions related to program updates and maintenance should be directed to the author.

## 2 Getting Started

This section describes how the example for **LAUFZE** can be started and executed. The simplest way to use the program for own travel-time calculations is to use the following examples and to modify the input data and parameters for your needs. The meaning and format of the contents of the input file are described in the following sections.

Installation of **LAUFZE**:

1) Make a sub-directory for **LAUFZE**, download the compressed tar-file containing the **laufze-software package**, decompress it, and run:

```
tar -xvf laufze.version.tar
```

You will then have a directory containing the following files and subdirectories:

*bin/ bin\_l/ examples/ man/ README src/*

The file *README* contains a complete list of all files included in the **laufze-software package** and a short explanation of these files.

2) If needed, recompile the software in the *src/* subdirectory by running:

```
make -f Makefile.laufze
```

and/or

```
make -f Makefile.laufps
```

The software was tested under UNIX as well under LINUX and should therefore run on both platforms without any compatibility problems. In the case of a LINUX system please use the corresponding *Makefiles* with the extension *\_linux\_g77* or *\_linux\_gfortran*, depending on your installed FORTRAN compiler.

3) Executing **LAUFZE**:

Change to the subdirectory *examples/*.

Here you will find an example for an input file.

To check your **LAUFZE** installation, try the following:

```
../bin/laufze
```

The program needs one input file in ASCII format. You will be asked for the name of the input file and here you answer with **laufze-in**. This file contains all parameters to steer the travel-time calculations and the layered velocity model. All results of the program are written in a file called **laufze-out**. The output file you get should be identical to the file **laufze-out.test** distributed with the **laufze-software package**. Contents and structure of these files will be explained in the following sections.

The program **LAUFPS** uses the same input file format as **LAUFZE** but it needs three files, one containing the P-velocity model and ray definitions for the requested P phases, one file containing the S-velocity model and ray definitions for the requested S phases and one file containing additional parameters to steer the requested converted phases for both P-to-S and S-to-P types of phase conversions. After starting the program with

```
../bin/laufps
```

you will be asked for names of the files containing the P- and S-velocity models and the file

to steer the behaviour of all P-to-SV and/or SV-to-P conversions (*e.g.*, *laufp-dat*, *laufs-dat*, and *laufps-in*). If you use the files as delivered with the *laufze-software package*, the LAUFPS output file *laufps-out* should be identical to the file *laufps-out.test*.

### 3 The File *laufze-in*

The file *laufze-in* must contain the velocity model for P (or S) waves and all information about the seismic phases for which travel times shall be calculated. The program asks for the name of the file containing this information in the format below described. The user can of course use any file name.

----- example for a *laufze-in* file -----

----- end of the example-----

```

The contents of the *laufze-in* file is as follows:

1. 1 line of maximum 80 characters with any explaining text as **TITLE**.
2. 1 line in FORMAT (3F10.3,3I5) containing the parameters: **RMIN**, **RMAX**, **VR**, **IELAS**, **NF11**.
 

**RMIN** is the beginning of the distance range from which onset times are calculated. Either measured in [deg] or in [km], see the definition of **VR**.

**RMAX** as **RMIN** but the end of the distance range used to print out the travel-time branches.

**VR** is the velocity or slowness to reduce the travel times.  
 If **VR** > 0, **RMIN** and **RMAX** are measured in [km] and **VR** is a reduction velocity [km/s].  
 If **VR** <= 0, **RMIN** and **RMAX** are measured in [deg] and **VR** is a reduction slowness [s/deg].

**IELAS** if this flag is set to 1,  $Q(z)$  is set to  $10^6$  in all depths (pure elastic case).

**NF11** if this flag is set to 1, no direct up-going rays from a source below the surface are calculated.
3. 1 line in FORMAT (2F10.3,3I5) containing the parameters: **PER**, **PERREF**, **LA1**, **LA2**, **NLA**.
 

**PER** is the dominant signal period  $T_{\text{sig}}$  [s].  
 If **PER** is set to 0 s, the default value of 1 s is used.

**PERREF** is the reference period  $T_{\text{ref}}$  [s].  
 If **PERREF** is set to 0 s, the default value of 1 s is used.

**LA1** is the number of the upper layer for the described reverberations (see V of the program options in the **Introduction**).

**LA2** as **LA1**, now the number of the lower layer.

**NLA** gives the number of reverberations.  
 The multiple phase travels **NLA** times more often through the depth range  $Z(\text{LA1}) \leq Z(I) < Z(\text{LA2})$  than the regular phase. If **LA1** = **LA2** or **NLA** = 0, no reverberations are calculated.
4. Now follows the model. The model is defined by one line for each depth with velocity information. All lines must fit in the FORMAT (2F10.3,A4,6x,F10.3) and contain the parameters **Z**, **V**, **AZ**, **QU**. The model can contain a maximum of 1000 layers. First

order discontinuities for one of the given parameters have to be defined by 2 lines in the same depth **Z**.

**Z** depth in [km] below the Earth's surface. The surface has the depth **Z**(1) = 0.

**V** seismic velocity in the depth **Z**.

**AZ** four characters long key words, with which one can define special actions in this depth:

= **SOUR** means that the seismic source is located in this depth of the model.

= **RECE** means that the 'receivers' are in this depth (to be set only if not at the surface, by default receivers are assumed to be at the surface).

= **SORE** means a combination of both **SOUR** and **RECE** in the same depth.

= **SURF** means that the seismic source is located in this depth and that for all (!) phases their corresponding surface reflections are additionally calculated (*e.g.*, pP, sScS, ...).

= **SURE** means a combination of both **SURF** and **RECE** in the same depth.

= **STRU** means that an up-going direct ray is reflected in this depth back down into the Earth (see IX of the program options in the **Introduction**).

If **STRU** is set at the surface, the classical surface reflection is calculated (*i.e.*, only pP or sS but not *e.g.*, pPP or sScS).

= **REFL** means that steep-angle reflections from this depth are calculated (see III of the program options in the **Introduction**).

**AZ** must be blank in all other cases.

**QU** is the quality factor for seismic waves in this depth; if **QU** = 0. the program sets it by default to **QU** = 1 000 000.

An empty line finishes the model input.

5. 1 line in FORMAT (3I5) with the three parameters **IS**, **IA**, **IB**.

**IS** = 0 the input model is assumed to be flat, *i.e.*, it consists of a set of horizontally flat layers.

= 1 the input model is spherical and has to be modified by the Earth-flattening transformation.

**IA** = I ; only the parts of the travel-time curves, which have their turning points below the I'th layer, are calculated. If **IA** = 1, all travel-time branches of all phases are calculated.

**IB** gives the number of rays, which will have their turning points between two given depth points of the model; an **IB** value of 10 – 20 usually gives a good approximation of the travel-time branch.

6. In the following line(s), the reflections of diving rays at any layer back down into the Earth can be defined (see IV of the program options in the **Introduction**). For each (!) such reflection 1 line in FORMAT (2I10) is needed with the parameters **IKMG** and **MULT**. If no (further) reflections of this type are to be calculated, one has to give a blank line.

**IKMG** is the number of the layer at which the ray is reflected; *e.g.*, for PP one has to set **IKMG** = 1.

**MULT** gives the number of reflections at this reflector (*e.g.*, for PP, SS, or PKKP one has to set **MULT** = 1, and for P3, S3, or S3KS one has to use **MULT** = 2).

7. Finally, multiple reflections for the steep-angle reflections as defined with **AZ** = **REFL** can be ordered with the following line(s) in FORMAT (I10) containing the parameter **MULTR**. No (further) multiples of this type have to be indicated by another blank line.

**MULTR** gives the number of additional multiples for each steep-angle reflection. **MULTR** = 1 will, for example, result in PmP2 (= PmPPmP) or ScS2 (= ScSScS) and **MULT** = 2 will give, *e.g.*, ScS3.

## 4 The File *laufze-out*

With the above listed example for a *laufze-in* file, you will obtain the output-file *laufze-out*. Please note that the output file has been truncated by numerous lines to reduce the number of pages in this manual. The ASCII listing of the travel times can easily be extracted and the user can plot them with any plotting program after some simple editing work. The original output file has 3117 lines and is included in the *laufze-software package*. Explanations are included in [ .... ]:

-----example for a *laufze-out* file -----

Travel times from LAUFZE 6.2

For a source in 100 km, Jeffreys-Bullen Model

[ Now followed the deleted PKPdf branch. ]

Surface reflection of the direct wave

[ See the parameters **STRU** and/or **SURF** in the input file. The ray output for pP, pPKP, and pPKiKP (over-critical part) was deleted. ]

P H A S E :

Diving wave      1-times reflected at the Earth's surface

[ See the parameters **IKMG** and **MULT** in the input file. The ray output for PP, P'P', and PKiKP2 (over-critical part) was deleted. ]

P H A S E :

Diving wave      2-times reflected at the Earth's surface

[ See the parameters **IKMG** and **MULT** in the input file. The ray output for P3, P'3, and PKiKP3 (over-critical part) was deleted. ]

P H A S E :

Diving wave      1-times reflected down at layer    21

[ See the parameters **IKMG** and **MULT** in the input file; layer 21 is here the core-mantle boundary. The ray output for PKKP and PKiKKiKP (over-critical part) was deleted. ]

P H A S E :

Diving wave      2-times reflected down at layer    21

[ See the parameters **IKMG** and **MULT** in the input file; layer 21 is here the core-mantle boundary (CMB). The ray output for P3KP and P3KiKP (over-critical part) was deleted. ]

P H A S E :

Steep-angle reflection from    2898.000 km

[ See the parameter **AZ = REFL** in the input file. Steep-angle reflection (*i.e.*, before the critical point) from the CMB; the ray output for PcP was deleted. ]

P H A S E :

Steep-angle reflection from    5121.000 km

[ See the parameter **AZ = REFL** in the input file. Steep-angle reflection (*i.e.*, before the critical point) from the ICB; the ray output for PKiKP was deleted. ]

P H A S E :

Multiple reflection (    1-times) for the  
Steep-angle reflection from    2898.000 km

[ See the parameters **AZ = REFL** and **MULTR** in the input file. Multiple steep-angle reflection (*i.e.*, before the critical point) from the CMB; the ray output for PcP2 was deleted. ]

P H A S E :

Multiple reflection ( 1-times) for the  
Steep-angle reflection from 5121.000 km

[ See the parameters **AZ** = **REFL** and **MULTR** in the input file. Multiple steep-angle reflection (*i.e.*, before the critical point) from the ICB; the ray output for PKiKP2 was deleted. ]

-----end of example for a *laufze-out* file -----

## 5 The Program LAUFPS and the File *laufps-in*

The program **LAUFPS** calculates travel-time curves for a given velocity model, as the program **LAUFZE** does, and was developed on the base of **LAUFZE**. In addition to **LAUFZE**, **LAUFPS** calculates P- and S-phase travel-time curves in one step and it can also calculate travel-time curves for converted phases. The input for **LAUFPS** consists of one steering and two model files:

One the model files contains the P-velocity model and one contains the S-velocity model. Both model files must have the same format as a **LAUFZE** input file, e.g., one file is then called *laufp-dat* and one *laufs-dat*. Both model files must sample the velocity models (*i.e.*, the P and the S model) at identical depths and the source must also be in the same depth. However, these input files can be extended at three points to inform the program in the case of multiple phases, how often these reverberations are eventually travelling through the model as converted phase. These additions are the following ones (I refer to the number of the format descriptions of the input-file for **LAUFZE**):

- 1 line in FORMAT (2F10.3,4I5) containing the parameters: **PER**, **PERREF**, **LA1**, **LA2**, **NLA**, **NLA2**.

**PER** is the dominant signal period  $T_{\text{sig}}$  [s].

If **PER** is set to 0 s, the default value of 1 s is used.

**PERREF** is the reference period  $T_{\text{ref}}$  [s].

If **PERREF** is set to 0 s, the default value of 1 s is used.

**LA1** is the number of the upper layer for the described reverberations (see V of the program options in the **Introduction**).

**LA2** as **LA1**, now the number of the lower layer.

**NLA** gives the number of reverberations.

The multiples travel through the depth range  $Z(\text{LA1}) \leq Z(I) < Z(\text{LA2})$  **NLA** times more than the regular phase. If **LA1** = **LA2** or **NLA** = 0, no reverberations are calculated.

**NLA2** gives how many of the **NLA** reverberations are travelling as converted phase (**NLA2** must be  $\leq \text{NLA}$ ).

6. In the following line(s) the reflections of diving rays at any layer back down into the Earth can be defined (see IV of the program options in the **Introduction**). For each (!) such reflection 1 line in FORMAT (3I10) is needed with the parameters **IKMG**, **MULT**, and **MULT2**. If no (further) reflections of this type shall be calculated one has to add a blank line.

**IKMG** is the number of the layer at which the ray is reflected; *e.g.*, for the surface reflection PP one has to set **IKMG** = 1.

**MULT** gives the number of reflections at this reflector (*e.g.*, for PP, SS, or PKKP one has to set **MULT** = 1, for P3, S3, or S3KS one has to use **MULT** = 2).

**MULT2** gives how many of the **MULT** reverberations are travelling as a converted phase (**MULT2** must be  $\leq$  **MULT**), *e.g.*, the travel-time curve of PPS will need to set **IKMG** = 1, **MULT** = 2, and **MULT2** = 1.

8. Finally, multiple reflections for the steep-angle reflections as defined with **AZ** = **REFL**, can be ordered with the following line(s) in FORMAT (2I10) containing the parameter **MULTR** and **MULTR2**. No (further) multiples of this type have to be indicated by another blank line.

**MULTR** give the number of multiples for each order steep-angle reflection. **MULTR** = 1 will *e.g.*, result in PmP2 or ScS2 and **MULT** = 2 will give *e.g.*, ScS3.

**MULTR2** gives how many of the **MULTR** reverberations are travelling as converted phase (**MULTR2** must be  $\leq$  **MULTR**), *e.g.*, the travel-time curve of PcPScS will need to set **MULTR** = 2, and **MULTR2** = 1.

The directory *examples/* contains files with one P- (*laufp-dat*) and one S-velocity model (*laufs-dat*) applying some of the mentioned settings.

In addition to these two model related files, the program **LAUFPS** needs one file containing steering parameters for each travel-time curve to define further phase conversions. It is recommended to run the program in a first step with setting the parameter **KONSAR** to 0 and then editing the steering file again. This steering file (here *e.g.*, called *laufps-in*) must contain the following information in the described format:

- a) In the first line the parameter **KONSOR** in FORMAT (I5). **KONSOR** steers the general behaviour of **LAUFPS**:

= 0 ; no conversions are calculated (not even the ones defined above!).  
 = 1 ; only conversions from P to SV type phases are calculated.  
 = 2 ; only conversions from SV to P type phases are calculated.  
 = 3 ; all types of conversions are calculated.

- b) For each (!) phase, as calculated in a first test run after setting **KONSOR** = 0 and then listed in *laufps-out* with an own phase header, one has to add one line with the parameters **KON**, **KON1**, **NDISK1**, **KON2**, **NDISK2** in FORMAT (5I5). For the test run, one can just add a large number of empty lines.

**KON** = 0 ; no conversion for this phase.

- = 1 ; this is a P phase and we get a P to SV conversion.
- = 2 ; this is an S phase and we get a SV to P conversion.
- = 9 ; the next entry is for the same phase but another conversion type.

**KON1** = 1 ; the first conversion happens on the ray path down.

- = 2 ; the first conversion happens on the ray path up.

**NDISK1** gives the discontinuity number for the first conversion: see the listing in the table in the *laufps-out* file.

**KON2** = 1 ; a possible second conversion happens on the ray path down.

- = 2 ; a possible second conversion happens on the ray path up.

**NDISK2** gives the discontinuity number for the second conversion.

```

## 12.1 Intensity and the history of intensity scales

Intensity can be defined as a classification of the strength of shaking at any place during an earthquake, in terms of its observed effects. The fact that it is essentially a classification, akin to the Beaufort Scale of wind speed, rather than a physical parameter, leads to some special conditions on its use. Principal among these is its being an integer quantity when assigned from observed data. Traditionally, Roman numerals have been used to represent intensity values to emphasise this point (it is hard to write "VII½"). Nowadays the use of Roman numerals is largely a matter of taste, and most seismologists find Arabic numerals easier to process by computer.

The word “macroseismic” is used to denote those effects of an earthquake that can be determined without the use of instruments. This includes intensity data but is not restricted to it. A list of places with associated intensity values is macroseismic data; so is the information that an earthquake was felt at a place, or caused damage there. The phrase “intensity data point” (IDP) refers to a datum specifying latitude, longitude and intensity (and usually location name). One also encounters “macroseismic data point” (MDP) in which the numerical intensity may be replaced by some code to indicate “felt”, “damage”, “heavy damage”, etc. The study of the felt effects of an earthquake is termed *macroseismology*. A contour line enclosing places where the intensity was predominantly equal to or higher than a certain value is called an *isoseismal*.

The use of intensity scales is historically important because no instrumentation is necessary, and useful measurements of an earthquake can be made by an unequipped observer. The earliest recognisable use of intensity was by Egen in 1828, although simple quantifications of damage had been made in the previous century by Schiantarelli in 1783 (Sarconi 1784), and some earlier Italian examples are said to exist. However, it was only in the last quarter of the 19th century that the use of intensity became widespread; the first scale to be used internationally was the ten-degree Rossi-Forel Scale of 1883. The early history of intensity scales can be found in Davison (1900, 1921, 1933), a later study can be found in Medvedev (1962), and see also the discussion on the evolution of scales in Musson et al (2010).

The scale of Sieberg (1912,1923) became the foundation of all modern twelve-degree scales. A later version of it became known as the Mercalli-Cancani-Sieberg Scale, or MCS Scale (Sieberg 1932), still in use in Southern Europe. The 1923 version was translated into English by Wood and Neumann (1931), becoming the inappropriately named Modified Mercalli Scale (MM Scale). This was completely overhauled in 1956 by Richter (1958) who refrained from adding his name to the new version in case of further confusion with "Richter Scale" magnitudes. Richter's version became instead the "Modified Mercalli Scale of 1956" (MM56) despite the fact that the link to Mercalli was now extremely remote. Local modifications of Richter's MM56 scale have been used in Australia and New Zealand. Later attempts to radically modernise the MM scale, such as that of Brazee (1978), did not catch on. Stover and Coffman's (1993) version of the scale consists of modifications to Wood and Neumann's (1931) version, bypassing Richter (1958). This version is now the most widely used, thanks to it being the basis of the popular “Did You Feel It?” system maintained by the USGS.

In 1964 the first version of the MSK Scale was published by Medvedev, Sponheuer and Karník (Sponheuer and Karník 1964). This new scale was based on MCS, MM56 and previous work by Medvedev in Russia, and greatly developed the quantitative aspect to make the scale more powerful. This scale became widely used in Europe, and received minor modifications in the mid 1970s and in 1981 (Ad-hoc Panel 1981). In 1988 the European

Seismological Commission agreed to initiate a thorough revision of the MSK Scale. The result of this work (undertaken by a large international Working Group under the chairmanship of Gottfried Grünthal, Potsdam) was published in draft form in 1993, with the final version released (after a period of testing and revision) in 1998 (Grünthal 1998). Although this new scale is more or less compatible with the old MSK Scale, the organisation of it is so different that it was renamed the European Macroseismic Scale (EMS). Since its publication it has been widely adopted inside and also outside Europe.

The one important intensity scale that does *not* have twelve degrees (now that the Rossi-Forel Scale is no longer much in use) is the seven-degree Japanese Meteorological Agency Scale (JMA Scale). This is based on the work of Omori, and is the scale generally used in Japan (but nowhere else). A recent modification to the JMA scale subdivides degrees 5 and 6 into upper and lower, and explicitly describes a degree 0, resulting in a ten-degree scale (JMA 1996, 2009). Also, the scale used in Taiwan up to 2000 ran from degree 0 to degree 6, but now includes a degree 7, making eight degrees in total (Wu et al, 2003).

A point to be stressed is that intensity in the modern understanding of the word is a measure of the strength of shaking of an earthquake, not just a list of things that may accompany an earthquake. Thus, for instance, tsunami observations bear no relation to intensity. It may be that in places where the intensity is high, there is also a strong tsunami – but one can also observe strong tsunami effects at great distances where the earthquake is not even felt, and an earthquake that does not displace the seabed will not produce a tsunami no matter how strong the shaking. The same stricture applies to secondary effects due to surface faulting.

To some extent the middle years of the 20th century saw a decline in interest in macroseismic investigation, with the improvements in instrumental monitoring. However, since the middle 1970s there has been a revival of interest in the subject since macroseismic data are essential for the revision of historical seismicity and of great importance in seismic hazard assessments. Macroseismic studies of modern earthquakes are vital for (i) calibrating studies of historical earthquakes; (ii) studying local attenuation, and (iii) investigations of vulnerability, seismic hazard and seismic risk.

The use of the internet as a medium for gathering data has proved an extremely powerful tool, and in developed countries a vast amount of data can be gathered and processed very rapidly, giving immediate information on the impact of an earthquake; information that formerly would not be available after the processing of many paper questionnaires, a work that could occupy months. The possibility of showing, via the internet, the distribution of effects of an earthquake within a matter of minutes or hours, is an excellent opportunity for communicating science to the public, and has attracted a lot of interest. The wealth of macroseismic data now readily available has renewed interest in intensity as an analogue for physical ground motion parameters, especially velocity (e.g. Ebel and Wald 2003, Kaka and Atkinson 2004, Boatwright et al 2006, Atkinson and Wald 2007).

## **12.2 Modern intensity scales**

The three most important intensity scales in current use are the European Macroseismic Scale (EMS-98), the Modified Mercalli Scale (MM or MMI) and the JMA scale, although the latter is not widely used in practice any longer to assign intensities. Each is given in turn here.

### 12.2.1 European Macroseismic Scale (EMS)

The complete EMS-98 scale is too long to reproduce in its entirety, being a small book in length. This is because, while historically intensity scales have been presented simply as a list of classes and diagnostics for the user to make of what he will, the EMS-98 scale comes with extensive support material, including guidelines, illustrations and worked examples. Even the traditional "core" part of the scale contains tabular and graphical material explaining the classification of buildings and quantities used.

Some intensity scales in the past, such as the Modified Mercalli scale (in its 1956 incarnation, Richter 1958) have attempted to distinguish between the effects of earthquake shaking on buildings of different construction types, using type as an analogue of strength. An essential feature of the EMS is that it employs a series of six vulnerability classes which represent strength directly, and involve construction type, but also other factors such as workmanship and condition. These vulnerability classes allow a flexible and robust approach to assessing intensity from damage. The system is also adaptable to new or different building types, and includes consideration of engineered structures with earthquake resistant design. Damage is handled in a way that discriminates between structural and non-structural damage, and the different forms damage takes in buildings of different types. A system of five damage grades is used: negligible to slight; moderate; substantial to heavy; very heavy, and destruction. These are not only defined but also illustrated pictorially (Figure 12.1).

The probabilistic nature of intensity is stressed by the use of numerically-defined expressions of quantity. For any intensity degree, it is expected that for buildings of equivalent strength there will be a modal level of damage that will be most frequently encountered, and decreasing proportions of the building stock of equivalent strength will show lesser or greater degrees of damage. This relates closely to real experience from damage surveys.

Although natural phenomena such as landslips, rockfalls, cracks in ground, etc., have been used in intensity scales for a long time, more recent experience has shown that the occurrence of these is very strongly influenced by other factors than the severity of earthquake shaking - especially pre-existing hydrological conditions. In the EMS, although these effects are not deleted entirely, they are relegated to an Annexe rather than being included in the core scale; they are treated in a graphical table which shows the ranges of intensities over which such phenomena are commonly (and exceptionally) encountered.

The full scale is published as Grünthal (1998). It can also be obtained in full at the following WWW address: <http://tinyurl.com/cp7dc2>

| Classification of damage to masonry buildings                                       |                                                                                                                                                                                                                                                                                                 |
|-------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|    | <b>Grade 1: Negligible to slight damage</b><br><b>(no structural damage, slight non-structural damage)</b><br>Hair-line cracks in very few walls.<br>Fall of small pieces of plaster only.<br>Fall of loose stones from upper parts of buildings in very few cases.                             |
|    | <b>Grade 2: Moderate damage</b><br><b>(slight structural damage, moderate non-structural damage)</b><br>Cracks in many walls.<br>Fall of fairly large pieces of plaster.<br>Partial collapse of chimneys.                                                                                       |
|   | <b>Grade 3: Substantial to heavy damage</b><br><b>(moderate structural damage, heavy non-structural damage)</b><br>Large and extensive cracks in most walls.<br>Roof tiles detach. Chimneys fracture at the roof line; failure of individual non-structural elements (partitions, gable walls). |
|  | <b>Grade 4: Very heavy damage</b><br><b>(heavy structural damage, very heavy non-structural damage)</b><br>Serious failure of walls; partial structural failure of roofs and floors.                                                                                                            |
|  | <b>Grade 5: Destruction</b><br><b>(very heavy structural damage)</b><br>Total or near total collapse.                                                                                                                                                                                           |

**Fig. 12.1** An example of the use of pictures in classifying damage grades in the European Macroseismic Scale

Despite the name of the scale (which reflects the fact that it was developed at the instigation of the European Seismological Commission), the scale is equally suitable for use outside of Europe, and has been used successfully for assessing modern earthquakes in many parts of the world. It is possible that the scale will be officially renamed in the near future to reflect this.

Here the short form (section 8 of the published scale) is reproduced. *This is not suitable for, and not intended for, use in assigning intensities.* It gives the character of each degree in a very simplified and generalised form for educational purposes.

### EMS Scale of 1998 (abstracted)

|             |                               |                                                                                                                                                                                                                                                                                                                                |
|-------------|-------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>I</b>    | <b>Not felt</b>               | Not felt.                                                                                                                                                                                                                                                                                                                      |
| <b>II</b>   | <b>Scarcely felt</b>          | Felt only by very few individual people at rest in houses.                                                                                                                                                                                                                                                                     |
| <b>III</b>  | <b>Weak</b>                   | Felt indoors by a few people. People at rest feel a swaying or light trembling.                                                                                                                                                                                                                                                |
| <b>IV</b>   | <b>Largely observed</b>       | Felt indoors by many people, outdoors by very few. A few people are awakened. Windows, doors and dishes rattle.                                                                                                                                                                                                                |
| <b>V</b>    | <b>Strong</b>                 | Felt indoors by most, outdoors by few. Many sleeping people awake. A few are frightened. Buildings tremble throughout. Hanging objects swing considerably. Small objects are shifted. Doors and windows swing open or shut.                                                                                                    |
| <b>VI</b>   | <b>Slightly damaging</b>      | Many people are frightened and run outdoors. Some objects fall. Some houses suffer slight non-structural damage like hair-line cracks and fall of small pieces of plaster.                                                                                                                                                     |
| <b>VII</b>  | <b>Damaging</b>               | Most people are frightened and run outdoors. Furniture is shifted and objects fall from shelves in large numbers. Many well built ordinary buildings suffer moderate damage: small cracks in walls, fall of plaster, parts of chimneys fall down; older buildings may show large cracks in walls and failure of fill-in walls. |
| <b>VIII</b> | <b>Heavily damaging</b>       | Many people find it difficult to stand. Many houses have large cracks in walls. A few well built ordinary buildings show serious failure of walls, while weak older structures may collapse.                                                                                                                                   |
| <b>IX</b>   | <b>Destructive</b>            | General panic. Many weak constructions collapse. Even well built ordinary buildings show very heavy damage: serious failure of walls and partial structural failure.                                                                                                                                                           |
| <b>X</b>    | <b>Very destructive</b>       | Many ordinary well built buildings collapse.                                                                                                                                                                                                                                                                                   |
| <b>XI</b>   | <b>Devastating</b>            | Most ordinary well built buildings collapse, even some with good earthquake resistant design are destroyed.                                                                                                                                                                                                                    |
| <b>XII</b>  | <b>Completely devastating</b> | Almost all buildings are destroyed.                                                                                                                                                                                                                                                                                            |

## 12.2.2 Modified Mercalli (MM) Scale

As stated, the situation regarding the MMI scale is confused. Most of the versions in circulation (e.g. on internet pages) are either the short form of the 1931 version, or some arrangement of the 1956 version. While papers frequently cite Stover and Coffman (1993) as the currently preferred version, one searches in vain for a copy of the scale according to Stover and Coffman (1993), since even Stover and Coffman do not present it in a unified form. Instead, they give Wood and Neumann's longer version, and a separate section in which they describe the modifications they apply in practice. Since this is the version of the scale that underlies the "Did You Feel It?" system (Wald et al 1999) and most of the recent studies on intensity and physical ground motion measures, the Stover and Coffman version is important, and it is strange that, hitherto, it seems to exist nowhere in print as an integrated scale.

Presented below is an attempt to give Stover and Coffman's 1993 version of MMI in one piece. This is not straightforward as it is not always clear precisely what Stover and Coffman's meaning is for some diagnostics, so a certain amount of editing has been necessary. Notable changes introduced by Stover and Coffman are that effects on people (other than loss of balance) are entirely removed from the scale above intensity 4. A number of other diagnostics are removed, and some are downgraded. The general result is that intensities assessed with this version are likely to be lower than before, especially in the range 4 to 7.

### MMI Scale of 1993 (Stover and Coffman, after Wood and Neumann, edited Musson)

- I** Not felt - or, rarely under especially favourable circumstances. Under certain conditions, at and outside the boundary of the area in which a great shock is felt: sometimes birds, animals, reported uneasy or disturbed; sometimes dizziness or nausea experienced; sometimes trees, structures, liquids, bodies of water, may sway - doors may swing very slowly.
- II** Felt indoors by few, especially on upper floors, or by sensitive, or nervous persons. Also, as in grade I, but often more noticeably: sometimes hanging objects may swing, especially when delicately suspended; sometimes trees, structures, liquids, bodies of water may sway; doors may swing very slowly; sometimes birds, animals reported uneasy or disturbed; sometimes dizziness or nausea experienced.
- III** Felt indoors by several, motion usually rapid vibration. Sometimes not recognized to be an earthquake at first. Duration estimated in some cases. Vibration like that due to passing of light, or lightly loaded trucks, or heavy trucks some distance away. Hanging objects may swing slightly. Movements may be appreciable on upper levels of tall structures. Rocked standing motor cars slightly.
- IV** Felt by many to all. Trees and bushes shaken slightly. Buildings shook moderately to strongly. Walls creaked loudly. Observer described the shaking as "strong." Awakened few, especially light sleepers. Frightened no one, unless apprehensive from previous experience. Vibration like that due to passing of heavy or heavily loaded trucks. Sensation like heavy body striking building or falling of heavy objects inside. Rattling of dishes, windows, doors; glassware and crockery clink and clash. Hanging objects

swung, in numerous instances. Disturbed liquids in open vessels slightly. Rocked standing motor cars noticeably.

- V** Buildings trembled throughout. Broke dishes, glassware, to some extent. Cracked windows - in some cases, but not generally. Overturned vases, small or unstable objects, in many instances, with occasional fall. Hanging pictures fall. Opened, or closed, doors, shutters, abruptly. Pendulum clocks stopped, started or ran fast, or slow. Moved small objects, furnishings, the latter to slight extent. Trees, bushes, shaken moderately to strongly. People have difficulty standing or walking. Felt moderately by people in moving vehicles.
- VI** Damage slight in poorly built buildings. Fall of plaster in small amount. Cracked plaster somewhat, especially fine cracks in chimneys in some instances. Broke dishes, glassware, in considerable quantity, also some windows. Fall of knickknacks, books, pictures. Overturned furniture in many instances. Moved furnishings of moderately heavy kind. Small bells rang - church, chapel, school, etc. The intensity can only be assessed as VI if damage to buildings is observed, unless many small objects fall from shelves or many glasses or dishes are broken.
- VII** Damage negligible in buildings of good design and construction, slight to moderate in well-built ordinary buildings, considerable in poorly built or badly designed buildings, adobe houses, old walls (especially where laid up without mortar), spires, etc. Cracked chimneys to considerable extent, walls to some extent. Fall of plaster in considerable to large amount, also some stucco. Broke numerous windows, furniture to some extent. Shook down loosened brickwork and tiles. Broke weak chimneys at the roofline (sometimes damaging roofs). Fall of cornices from towers and high buildings. Dislodged bricks and stones.
- VIII** Damage slight in structures (brick) built especially to withstand earthquakes. Considerable in ordinary substantial buildings, partial collapse: racked, tumbled down, wooden houses in some cases; threw out panel walls in frame structures, broke off decayed piling. Fall of walls. Cracked, broke, solid stone walls seriously. Twisting, fall, of chimneys, columns, monuments, also factory stacks, towers. Moved conspicuously, overturned, very heavy furniture. Trees shaken strongly - branches, trunks, broken off, especially palm trees.
- IX** Damage considerable in (masonry) structures built especially to withstand earthquakes: threw out of plumb some wood-frame houses built especially to withstand earthquakes; great in substantial (masonry) buildings, some collapse in large part; or wholly shifted frame buildings off foundations, racked frames.
- X** Damage serious to dams, dykes, embankments. Severe to well-built wooden structures and bridges, some destroyed. Developed dangerous cracks in excellent brick walls. Destroyed most masonry and frame structures, also their foundations.
- XI** Damage severe to wood-frame structures, especially near shock centres. Great to dams, dikes, embankments often for long distances. Few, if any (masonry) structures remained standing. Destroyed large well-built bridges by the wrecking of supporting piers, or pillars. Affected yielding wooden bridges less.
- XII** Damage total - practically all works of construction damaged greatly or destroyed.

**Notes:** It is ambiguous in the text of Stover and Coffman (1993) whether the section of diagnostics for intensity 4 beginning “Awakened few ...” and ending “Rocked standing motor cars noticeably” is intended to be included in the scale or not. USGS practice is to include them (Dewey 2009 *pers. comm.*). According to some sources, e.g. Boatwright and Bundon (2005), the revisions of Stover and Coffman (1993) include treating the fall of few chimneys as intensity 6 and the fall of half of all chimneys or more as 7. This is not actually found anywhere in Stover and Coffman (1993).

### 12.2.3 Japan Meteorological Agency (JMA) Scale

The JMA scale has evolved over the years from the seven-degree scale of Omori (1900). The revision of 1996 added two new degrees, but to try and maintain consistency with older data sets, the new scale divided degree 5 into “5 Lower” and “5 Upper”, and similarly for degree 6. The latest revision in 2009 maintains this system, but the scale is reworded and revised throughout, and is generally greatly improved in clarity and cohesiveness.

However, routine practice in Japan seems to be largely to rely on estimates of intensity made by customised strong-motion instruments. The scale is therefore a guide to what might be expected to happen in a place where the local intensity instrument registers a given value; it is not a means of recording what actually was observed. Thus the scale notes that at intensities above 4, railway services may be suspended for safety checks. No-one would use that information to assign intensity, but it is useful information for people affected by an earthquake.

#### JMA Scale of 2009 (re-arranged)

|                  |                                                                                                             |
|------------------|-------------------------------------------------------------------------------------------------------------|
| <b>0</b>         | <i>Effects on</i>                                                                                           |
| <i>People:</i>   | Imperceptible to people.                                                                                    |
| <b>1</b>         | <i>Effects on</i>                                                                                           |
| <i>People:</i>   | Felt slightly by some people keeping quiet in buildings.                                                    |
| <b>2</b>         | <i>Effects on</i>                                                                                           |
| <i>People:</i>   | Felt by many people keeping quiet in buildings. Some people may be awoken.                                  |
| <i>Indoors:</i>  | Hanging objects such as lamps swing slightly.                                                               |
| <b>3</b>         | <i>Effects on</i>                                                                                           |
| <i>People:</i>   | Felt by most people in buildings. Felt by some people walking. Many people are awoken.                      |
| <i>Indoors:</i>  | Dishes in cupboards may rattle.                                                                             |
| <i>Outdoors:</i> | Electric power lines swing slightly.                                                                        |
| <b>4</b>         | <i>Effects on</i>                                                                                           |
| <i>People:</i>   | Most people are startled. Felt by most people walking. Most people are awoken.                              |
| <i>Indoors:</i>  | Hanging objects such as lamps swing significantly, dishes in cupboards rattle. Unstable ornaments may fall. |

*Outdoors:* Electric wires swing significantly. Those driving vehicles may notice the tremor.

**5 Lower** *Effects on*

*People:* Many people are frightened and feel need to hold onto something stable.

*Indoors:* Hanging objects such as lamps swing violently. Dishes in cupboards and items on bookshelves may fall. Many unstable ornaments fall. Unsecured furniture may move, and unstable furniture may topple over.

*Outdoors:* In some cases, windows may break and fall. People notice electricity poles moving. Roads may sustain damage.

*Wooden houses (low earthquake resistance):* Slight cracks may form in walls.

*Ground and slopes:* Small cracks in ground may form and liquefaction may occur. Liquefaction may be seen in areas with a high groundwater level and loose sand deposits. Damage observed as a result of liquefaction includes spouts of muddy water from the ground, outbreaks of subsidence in riverbanks and quays, elevation of sewage pipes and manholes, and leaning or destruction of building foundations. Rock falls and landslips may occur.

*Utilities and infrastructure:* In the event of shaking with a seismic intensity of about 5 Lower or more, gas meter with safety devices are tripped, stopping the supply of gas. In the event of stronger shaking, the gas supply may stop for entire local blocks. Suspension of water supply and electrical blackouts may occur in regions experiencing shaking with a seismic intensity of about 5 Lower or more. In the event of shaking with a seismic intensity of about 5 Lower or more, elevators with earthquake control devices will stop automatically for safety reasons.

**5 Upper** *Effects on*

*People:* Many people find it hard to move; walking is difficult without holding onto something stable.

*Indoors:* Dishes in cupboards and items on bookshelves are more likely to fall. TVs may fall from their stands, and unsecured furniture may topple over.

*Outdoors:* Windows may break and fall, unreinforced concrete-block walls may collapse, poorly installed vending machines may topple over, automobiles may stop due to the difficulty of continued movement.

*Wooden houses (low earthquake resistance):* Cracks may form in walls.

*Reinforced concrete buildings (low earthquake resistance):* Cracks may form in walls, crossbeams and pillars.

*Ground and slopes:* As 5 Lower.

**6 Lower** *Effects on*

*People:* It is difficult to remain standing.

*Indoors:* Many unsecured furniture moves and may topple over. Doors may become wedged shut.

*Outdoors:* Wall tiles and windows may sustain damage and fall.

*Wooden houses (low earthquake resistance):* Cracks are more likely to form in walls. Large cracks may form in walls. Tiles may fall, and buildings may lean or collapse.

*Wooden houses (high earthquake resistance):* Slight cracks may form in walls.

*Reinforced concrete buildings (low earthquake resistance):* Cracks are more likely to form in walls, crossbeams and pillars.

*Reinforced concrete buildings (high earthquake resistance):* Cracks may form in walls, crossbeams and pillars.

*Ground and slopes:* Cracks in ground may form. Landslips and landslides may occur.

## **6 Upper**

### *Effects on*

*People:* It is impossible to remain standing or move without crawling. People may be thrown through the air.

*Indoors:* Most unsecured furniture moves, and is more likely to topple over.

*Outdoors:* Wall tiles and windows are more likely to break and fall. Most unreinforced concrete-block walls collapse.

*Wooden houses (low earthquake resistance):* Large cracks are more likely to form in walls. Buildings are more likely to lean or collapse.

*Wooden houses (high earthquake resistance):* Cracks may form in walls.

*Reinforced concrete buildings (low earthquake resistance):* Slippage and X-shaped cracks may be seen in walls, crossbeams and pillars. Pillars at ground level or on intermediate floors may disintegrate, and buildings may collapse.

*Reinforced concrete buildings (high earthquake resistance):* Cracks are more likely to form in walls, crossbeams and pillars.

*Ground and slopes:* Large cracks in ground may form. Landslips are more likely to occur; large landslides and massif collapses may be seen. When large landslides and massif collapses occur, dams may form depending on geographical features, and debris flow may occur due to the large quantities of sediment produced.

*Utilities and infrastructure:* In the event of shaking with a seismic intensity of 6 Upper or more, gas, water and electric supplies may stop over wide areas.

## **7**

### *Effects on*

*People:* It is impossible to remain standing or move without crawling. People may be thrown through the air.

*Indoors:* Most unsecured furniture moves and topples over, or may even be thrown through the air.

*Outdoors:* Wall tiles and windows are even more likely to break and fall. Reinforced concrete-block walls may collapse.

*Wooden houses (low earthquake resistance):* Buildings are even more likely to lean or collapse.

*Wooden houses (high earthquake resistance):* Cracks are more likely to form in walls. Buildings may lean in some cases.

*Reinforced concrete buildings (low earthquake resistance):* Slippage and X-shaped cracks are more likely to be seen in walls, crossbeams and pillars. Pillars at ground level or on intermediate floors are more likely to disintegrate, and buildings are more likely to collapse.

*Reinforced concrete buildings (high earthquake resistance):* Cracks are even more likely to form in walls, crossbeams and pillars. Ground level or intermediate floors may sustain significant damage. Buildings may lean in some cases.

*Basic infrastructure:* Electrical, gas, and water supplies are interrupted over a large area.

*Ground and slopes:* As 6 Upper.

## **Notes:**

Wooden houses and RC buildings are classified into two categories according to their earthquake resistance, which tends to be higher for newer structures. Earthquake resistance tends to be low for structures built up to 1981, and high for those built since 1982. However,

to maintain a certain range of earthquake resistance according to differences in structure and wall arrangement, resistance is not necessarily determined only by building age. The earthquake resistance of existing buildings can be ascertained through quakeproofing diagnosis.

The walls of wooden houses are assumed to be made of mud and/or mortar. Mortar in a wall with a weak base can easily break off and fall, even under conditions of low deformation. Damage to wooden houses depends on the period and duration of seismic waves. In some cases (such as the Iwate-Miyagi Nairiku Earthquake of 2008), few buildings sustain damage in relation to the level of seismic intensity observed.

## **12.3 Collection of macroseismic data**

Collection of macroseismic data from current earthquakes is derived principally from two sources - questionnaire surveys and field investigations, either or both of which may be required for a particular earthquake. As a general rule, questionnaire surveys are used for assessing intensities in the range of 2 to 6, while for 7 and above field investigations are necessary. Questionnaires used to be distributed predominantly as paper documents, to be filled in and returned to the investigator. Since about 2000, this has been progressively replaced by internet collection of data.

One thing in common with both questionnaire surveys and field investigations is the desirability of rapid response - evidence of earthquake damage is patched up within days or even hours, and human memory of details (and interest in the subject) also wanes rapidly. There is a third source - documentary material, for instance, newspaper accounts - which is the principal source of macroseismic data for historical earthquakes. The treatment of this is a separate subject involving the techniques of the professional historian as well as the seismologist, and is not dealt with here.

A general point common to both paper and internet questionnaires is the problem of geo-location. One cannot ask people to give their location in terms of latitude and longitude, and interpreting addresses from a large number of questionnaires would be too onerous. So the usual practice is to rely on postcodes (zip codes). The problem here is that different countries use different systems with different resolutions, so in one country the postcode may be convertible to a co-ordinate location with accuracy of tens of metres, while in another, the accuracy may not be better than tens of kilometres.

In either case, someone who fills in a questionnaire for an earthquake he felt other than at home, may not know the postcode of the location where he was – and may simply put in his home postcode, a potential source of error in the data.

### **12.3.1 Macroseismic questionnaires, pre-internet**

When dealing with traditional macroseismology, when surveys of earthquake effects had to be conducted using paper forms and the postal service, one could distinguish two basic types of macroseismic questionnaire, dependant on the intended recipient. The first is the questionnaire to be answered by an individual citizen recounting his personal experiences of the earthquake. The second is the questionnaire designed to be answered by someone with knowledge of the experiences of the entire community. Which of these two approaches is

used will shape the macroseismic investigation as a whole; the choice may well be forced on the investigator by circumstances. For example, in some countries there will be found an official in each town or rural community whose job includes completing such requests for data, and who can be relied on to fill in any questionnaire submitted. In some other countries such officials are not to be found, and this means of investigation is therefore not possible. Some institutes may have the resources to post out thousands of questionnaires as mailing shots; others may not be able to afford such a technique.

One may discern four basic types of person who may fill in a macroseismic questionnaire, two in each of the classes outlined above.

- (i) *The unselected individual* - questionnaires may be distributed haphazardly and in great bulk by publication in newspapers, dissemination at libraries, etc. This guarantees a large response, but probably biases the results in favour of positive responses.
- (ii) *The randomly selected individual* - there exists a methodology, highly developed in the social sciences, for disseminating questionnaires in such a way as to maximise the statistical validity of the results, using random selection procedures based on electoral rolls and direct mailing, often with some incentive to return the questionnaire (such as a prize draw). This is the best method in terms of the reliability of the results, since a random sample enables one to make statistically valid estimations of the characteristics of the whole population. The drawbacks are that such a response may be difficult to organise rapidly after an earthquake, and is likely to be relatively expensive. It should not be forgotten, that the art of questionnaire design and methodology has been studied in detail by social scientists for many years, and the expertise accumulated should not be ignored by seismologists whose background usually lies in the physical sciences.
- (iii) *The public official* - it is very convenient to be able to send a single questionnaire to the local burgomaster/postal officer/police superintendent's office and have it filled in with the details of the effects of the earthquake in the whole of the community under the official's jurisdiction. What the seismologist cannot be certain of is how conscientiously the questionnaire is filled in. Does the official make detailed enquiries, or does he jot down the first thing that comes into his head?
- (iv) *The volunteer* - some seismological institutes arranged networks of local volunteers with some standing in the community (schoolteachers, clergymen) and enthusiasm for the task of supplying useful data. Such volunteers can be given a stack of blank questionnaires in advance and can be relied upon to fill one in after an earthquake occurs with dependable data on the effects in the locality. Such a system is very effective, but can be laborious to set up and maintain. An advantage of such a system is that one stands a good chance of getting reliable negative information.

A further division of questionnaire design is that between the free-form questionnaire and the multiple choice style. The first style gives open-ended questions to which the respondent can answer in his own words ("What sort of shaking did you experience?") while the second gives a series of boxes to tick ("The shaking was A - weak; B - moderate; C - strong"). The second style is easier to process, but runs the risk of losing information that doesn't easily fit the predefined categories. A combination of both styles is also possible.

Length of questionnaire is also important. Too long or difficult a questionnaire will discourage people from filling it in, as will asking questions that are too hard for most people

to answer - for example, how many people can accurately describe their local geology? One should guard against asking questions that are not strictly necessary (such as personal details). From the above discussion it will be seen that questionnaire design is somewhat of an art, and that what will work for one country won't work for another.

A sample of a typical paper questionnaire for distribution after an earthquake is given in section 12.3.3 below.

### **12.3.2 Macroseismic questionnaires, post-internet**

The use of the internet as a tool for collecting macroseismic data has transformed the subject over the first decade of the 21<sup>st</sup> century, at least in developed countries where the use of the internet in ordinary homes is widespread. Not only can data be collected in very large volumes very rapidly, it can also be processed in real time and the results displayed immediately. The adoption of such a system answers definitively the question discussed in the previous section as to who is expected to provide the response – internet questionnaires will be completed by ordinary persons, who visit the institute's web site and choose to record their experience. The internet questionnaire will therefore be designed to capture this type of individual experience, from persons lacking technical expertise. It does mean that the sample is always self-selecting, and therefore will tend to be biased in favour of positive responses. Automatic processing routines favour the collection of data where answers are predefined between several options, so a check-box approach will usually be most appropriate, though space should be provided to allow for extra comments to be written in; these will need to be read individually by the investigator.

It was difficult in the past to produce a standard macroseismic questionnaire that could be used internationally, because of the different types of respondent in different countries. However, since all internet questionnaires are directed at ordinary individuals, there is a real possibility that a single standard questionnaire could be developed. Indeed, both the USGS and EMSC have collected data for earthquakes in many different countries, according to standard questionnaire formats.

The main obstacle to a single unified questionnaire is that internet questionnaires are to some extent shaped by the intensity scale in use and the system that will be used to process the data. This is likely to vary from country to country still, due to a desire to maintain compatibility with past data sets. The establishment of a global standard questionnaire, from which national institutes can select subsets of questions as desired, is still a realisable goal. Currently, a draft standard internet questionnaire has been drawn up by the ESC Working Group on Internet Macroseismology.

Examples of online questionnaires can be seen on the USGS (<http://earthquake.usgs.gov/earthquakes/dyfi/>) and EMSC (<http://www.emsc-csem.org/Earthquake/felt.php>) websites, among others.

### 12.3.3 Sample questionnaire

#### EARTHQUAKE QUESTIONNAIRE

The following questionnaire is part of a study of the effects of the \_\_\_\_\_ (name) earthquake, which occurred on \_\_\_\_\_ (date) at \_\_\_\_\_ (time). You are invited to use it to record what you experienced.

If you did NOT feel the earthquake, or notice it at all, please tick here [ ] and complete questions 1, 2 and 5, below. This information will still be useful for our study. Please send completed questionnaires to this address:

.....  
.....  
.....

#### SECTION A – WHERE YOU WERE

1. At the time of the earthquake, where were you?

Address (including post code).....

Outdoors [ ]                      Ground floor [ ]                      Upper floor [ ] ; If so, which floor?

Stationary vehicle [ ]                      Moving vehicle [ ]                      Other \_\_\_\_\_

If indoors, please describe the type of building:

Function (house, school, church, etc) .....

Height (number of stories) .....

Construction (brick, stone, wood, etc) .....

2. What were you doing?

Walking [ ]                      Standing [ ]                      Sitting [ ]                      Kneeling [ ]

Lying down [ ]                      Sleeping [ ]

#### SECTION B – EARTHQUAKE SHAKING AND SOUND

3. What best describes the shaking you felt?

No shaking [ ]                      Trembling [ ]                      Swaying [ ]                      Jerky motion [ ]

Impact [ ]                      Rolling motion [ ]                      Other [ ] .....

It was ...    Weak [ ]                      Moderate [ ]                      Severe [ ]

4. What best describes any sound you heard?

No sound [ ]                      Rumbling [ ]                      Roaring [ ]                      Explosion [ ]

Other [ ] .....

It was ...    Faint [ ]                      Moderate [ ]                      Loud [ ]

#### SECTION C – EFFECTS ON PEOPLE AND ANIMALS

5. Which best describes what happened where you were (your house, neighbours)?

Nobody noticed it [ ]                      Only one or two people noticed it [ ]  
 Some people noticed it, but not many [ ] Many people noticed it [ ]  
 Most people noticed it [ ] Everyone noticed it [ ]  
 People indoors noticed it, but not those outside [ ]  
 People upstairs noticed it, but not those on the ground floor [ ]  
 I don't know whether other people noticed it or not [ ]

6. (Only for earthquakes that happened at night) Did the earthquake wake you?  
 No [ ]      Yes [ ]              I wasn't asleep [ ]  
 Were other people where you were woken up?  
 No [ ]      Yes, a few [ ]    Yes, many [ ]    Yes, most/all [ ]                      Don't know [ ]
7. Were you frightened?  
 No [ ]      Yes [ ]  
 Where you were, did anybody run outdoors in fright?  
 No [ ]      Yes, a few [ ]    Yes, many [ ]    Yes, most/all [ ]                      Don't know [ ]
8. Was it hard to stand or walk?  
 No [ ]      Yes, a bit [ ]    Yes, very [ ]

#### SECTION D – EFFECTS ON OBJECTS, BUILDINGS, ETC

9. Did any of the following things happen?
- |                                  | Yes | No  | Don't know |
|----------------------------------|-----|-----|------------|
| Windows/doors rattled            | [ ] | [ ] | [ ]        |
| Crockery, etc rattled            | [ ] | [ ] | [ ]        |
| Hanging objects swung            | [ ] | [ ] | [ ]        |
| Pictures moved askew or fell     | [ ] | [ ] | [ ]        |
| Small objects shifted or fell    | [ ] | [ ] | [ ]        |
| Books or similar shifted or fell | [ ] | [ ] | [ ]        |
| Furniture shook visibly          | [ ] | [ ] | [ ]        |
| Furniture shifted out of place   | [ ] | [ ] | [ ]        |
| Furniture toppled over           | [ ] | [ ] | [ ]        |
| Liquids splashed or spilled      | [ ] | [ ] | [ ]        |
- Please give details, or note any other things that you noticed:.....  
 .....
10. Was there any damage to buildings where you were?  
 No [ ]      Yes [ ]              Don't know [ ]  
 If yes, please describe the damage .....  
 .....  
 .....
11. Were there any effects on natural surroundings where you were, for example, landslips, cracks in ground, effects on ponds or streams, etc?  
 No [ ]      Yes [ ]              Don't know [ ]  
 If yes, please describe the effects .....  
 .....  
 .....  
 .....
12. Have you any other comments about the effects of the earthquake that might be useful?

### **12.3.4 Field investigations**

Earthquakes can't be predicted; but one can know, in any region, the events that are likely to occur at some time or other, and one can at least partially prepare in advance. As always in macroseismology, there is no fixed rule how to do things, because how one proceeds will heavily depend on the size of the earthquake, its location and the importance of the data for the overall knowledge of the seismicity of the area. For example, an earthquake of intensity 6 will not surprise anyone in Italy or Greece, and will probably be surveyed only briefly, but such event in Finland or Denmark might be one of the strongest felt in a very long period, and therefore would be studied very much in detail.

There are quite a few distinctions in procedure in dealing with an event with only minor (non-structural) damage and a more severely damaging one.

Field work in macroseismology in general can be divided in three main phases: preparation, the field activities themselves, and finally later activities. The following issues need to be discussed: arranging teams of investigators, providing equipment, arranging travel and accommodation, methods of investigation, and ensuring safe working practices.

#### **12.3.4.1 Preparation – before the earthquake occurs**

Some preparation should be done on a contingency basis, before any earthquake has occurred; this minimises the amount of time needed arranging things between the occurrence of the earthquake and the setting out of the field investigation team.

The first issue is building a roster of potential participants in field investigations. These may be observatory staff (seismologists) but may also include other seismologists, either from other institutes in the same country or from abroad (especially neighbouring countries; cross-border earthquakes may need to be considered). In case of an earthquake strong enough to cause structural damage, it is essential to be able to call on the help of one or more civil engineers with experience in earthquake engineering. The help of a geotechnical engineer or engineering geologist will also be needed in cases of high-intensity earthquakes. In cases that it is expected that international team members will be called in who do not speak the local language, suitable translators should be available. Names and phone numbers of potential team members should be compiled in advance.

In some cases it may be useful to include team members with less experience, for training purposes, though this is not recommended for earthquakes that are humanitarian disasters.

Equipment (discussed in detail below) needs to be collected in advance and stored for use when needed, and checked at regular intervals to make sure that things like batteries are in a state of readiness.

Procedures for arranging travel can also be made in advance, for fast issuing of tickets, travel insurance and other travel documents. If the observatory does not have its own vehicles, arrangements should be in place for quick availability of rented vehicles (and in extreme cases of very strong earthquakes, a helicopter will probably be needed).

Additional items to consider: a list of passport/identity cards/driving licenses expiry dates of all team members, to be checked regularly so that the documents can be updated in time; a list of passwords for remote connections, for laptops, and pin numbers of mobile phones.

#### **12.3.4.2 Preparation – after the earthquake occurs**

Immediately after the earthquake has occurred, the actual field investigation can be prepared, in the light of the severity of the event and its actual location. In the case of earthquakes causing only minor damage, a quick arrival into the field is essential, as damage will swiftly be made good and debris swept away. In the case of major earthquakes causing severe damage and many casualties, rapid response is less essential (ruined buildings will not be cleared so quickly) and may even be a bad idea, as priority must be given to rescue work. Scientific investigation should not be allowed to hinder or compromise humanitarian relief.

For an earthquake of intensity up to 6 it is usually enough that two people spend a few days in the field. If the earthquake was felt in a large town, an additional day spent collecting data in schools can be useful. Of course, it depends how important the earthquake is for the knowledge of the seismicity of the region. In countries with low seismicity such earthquake would definitely justify more work than elsewhere. For a severe earthquake, one should expect that around six people (two groups of three) should work for four or five days, though this can vary according to the situation and resources.

Travel arrangements vary very much depending on the size of the event, the level of destruction and the distance from the epicentral area to the starting point of the team. In the majority of cases, a car or several cars will be enough. In case of a major earthquake, one might consider aerial survey (plane, helicopter) to get an idea of the situation in the most damaged area. Public transport might be not available in the affected area, so one cannot rely on it. If the nearby airfields are closed, the teams might need to use humanitarian or rescue flights; for this, it would be advisable to establish contacts in advance and keep the contact data updated.

Regarding accommodation, a centrally placed hotel is ideal when dealing with relatively minor earthquakes, but in cases of major events with strong aftershock sequences, one should choose a hotel well away from the epicentral area. In extreme cases, for instance if the damaged area is difficult to access by road, or the area of destruction is very large, it may be necessary to camp in tents.

When dealing with a strongly damaging earthquake it will be essential to liaise with the civil authorities in advance of arriving in the damage zone, to arrange authorisation and access. After the 2010 Haiti earthquake, remote sensing data was made available rapidly, from which it was possible to identify the worst damaged areas, and locations of landslides and other major ground failures. This sort of data is likely to continue to be available in the future, at least for major disasters, and may be extremely useful in planning locations to visit.

Lastly, point of contact arrangements should be made with observatory staff back at base, with the team making contact regularly (usually once a day, in the evening) to report that all are safe.

#### 12.3.4.3 Equipment

The equipment that will be needed can be divided into two: items that are always needed, and items needed when investigating areas with structural damage.

The basic items are the following:

- Maps, road navigation devices/GPS, cameras, extra sets of batteries, laptop, notebooks, portable voice recorder, tape measure, copy of the intensity scale.
- Optionally, one may wish to carry printed questionnaires (especially if one intends to visit some schools) when dealing with earthquakes with limited damage. Also educational material (especially guidelines to earthquake safety) could be carried, and again, this is particularly useful in case of visits to schools.
- Clothes and shoes should be chosen depending on the weather conditions and the type of terrain. If the investigation will last several days, and conditions are likely to be difficult (e.g. weather is bad) then special care should be taken in choosing clothing. Clothes should be comfortable to wear and not complicated to take care of. Sturdy shoes, materials, that behave well in rain (jeans can be impractical when wet), jackets, hats and mittens, and multilayered clothing is recommended. Basics like sunglasses, insect repellent, sunscreen should not be forgotten.
- When in a damaged area, safety clothing is essential. This means a helmet, high-visibility jacket, and steel-tipped boots. The jacket should preferably be marked clearly with the name of the institute or field investigation team. It can be very difficult to access the epicentral area without very visible identification (Figure 12.2).

**Fig. 12.2** Italian seismologists making a macroseismic field investigation after the 2009 L'Aquila earthquake: note the safety helmets and high-visibility jackets clearly marked with the institute name.

- In general, clothes with the institute logo are useful, and IDs with photographs should be carried at all times. Residents are sometimes suspicious of people going round photographing houses.
- In case of a high intensity earthquake it might be necessary for a team to use a tent; so camping equipment needs to be available, and regularly checked/renewed as well: tents, sleeping bags, cooking equipment, etc. Lamps, flashlights, batteries and first aid kits should be ready, as well as dry food and water for a few days. Disaster zones can be insanitary, so water purification, surgical masks, and gloves may be needed.

#### **12.3.4.4 In the field**

In dealing with a relatively low-intensity event, a visit to epicentral area should include a short stay in each (or at least in a representative number) of the damaged localities. Each locality should be surveyed on foot (if small) or by car, to get the overview of the situation and to note the extreme cases of damage. Contact with local authorities is recommended; information about damage can be found from the emergency services, insurance agencies and just talking to people. Schools are a good source of information – if there are enough team members, one can spend a few hours visiting the local school, especially if it is in a rural setting, where children are being brought from a wider area. In villages it is often enough to stop in the shop or in the pub, these being the points where many people come and talk to each other. One can consider leaving some printed questionnaires with some person willing to conduct a small survey and send back the answers, or at a local library or post office.

The team will usually split up into pairs or trios, one pair per car. While one drives, the other one can deal with the collected information, study maps, take phone calls etc. In the ideal case the pairing should consist of one seismologist and one civil engineer. In case of geotechnical issues (liquefaction, etc), an engineering geologist or geotechnical engineer should accompany them. In practice, a team member can be anyone working in seismology, with working knowledge of the scale and some basic training in recognising the building type and grade of damage. For low intensity earthquakes, it is not expected that there would be language barriers between the team and the inhabitants of the epicentral area, as the investigation would be made only by members of local institutes; in case of language differences, it is recommendable to have an interpreter along as well. For large earthquakes, the size of the team can vary during the time of the survey, as more participants can arrive later, if necessary, and the team members may be changed according to circumstances.

As a rule, if all the damage is non-structural, a team consisting only of seismologists is sufficient. Once structural damage needs to be registered, the assistance of a civil engineer becomes essential.

In the field, it is necessary to combine both detailed and general surveys of structural behaviour. Structures need to be surveyed in terms of: the distribution of different types; the overall vulnerability (resistance or lack of resistance to earthquake shaking) of typical structures while noting deviations in terms of good or bad examples; and the distribution of different grades of damage within each building type. Care should be taken over making accurate records of the location of all structures studied or photographed. Data should be gathered as written notes and photographs.

For engineered structures, a detailed study should be carried out to identify both good and bad performance in a sample of both damaged and undamaged structures. Both external and internal damage should be recorded if safe to do so (bearing in mind that entering damaged buildings may be too dangerous), identifying typical modes of failure. In order to be able to relate the damage to the intensity scale, information on the strength of the building is required: strengths and weaknesses in the construction techniques, special points of vulnerability, or high resistance, irregularity or symmetry in the building design, the quality of the materials used, and so on. It is a good idea to collect information on what earthquake-resistant design regulations were in force before the earthquake, and also, where possible, to investigate to what extent these regulations were followed in the buildings examined.

The case is similar for non-engineered structures; these are likely to be less individual, so the task becomes one of identifying the main characteristic structural forms, their age and condition. Again, the extent and types of damage, both interior and exterior, need to be recorded.

Detailed photographic surveys can be made of individual streets or districts to record the percentages of various types of buildings that were damaged to a lesser or greater degree. These surveys should be supplemented with internal records from at least a sample of the buildings examined.

The overall spatial distribution of damage can be recorded over a large area by the use of general surveys employing proper sampling techniques to generate statistically consistent data. Distinctions between different construction types, usage, height and age and quality of construction should always be made wherever possible.

Geotechnical aspects should also be investigated. Any relationship between local geology and damage distribution should be investigated. (This does not entail “correcting” intensities for local conditions, but does explain local variations in observed intensity). Data should be gathered on groundwater and hydrological conditions before the earthquake. The following topics also need to be considered: types of foundation and their performance; effects on embankments, cuttings and river banks; liquefaction and other ground effects like cracking; landslides and rockfalls. Negative data as well as positive data should be collected.

Special studies may be needed of individual industrial or civil facilities. Effects on factories can include damage to pipework and ducting, pumps and valves, cabling systems, tanks, machinery, electrical controls, computers and cranes. The effects on dams, bridges, port facilities, tunnels and irrigation systems should be recorded. The effects on lifelines (services, transport) also merit attention: underground provision of water, gas, electricity and telecommunications; railways, roads etc. These sorts of data are not generally suitable for intensity assessment per se, but are important to record, particularly when making an assessment of the economic impact of the earthquake, or looking at lessons to be learnt from an engineering perspective.

One should not forget that for intensity evaluation the data be statistically representative, and in larger settlements this is difficult to achieve. Therefore, the teams should not lose too much time on a single building, but try to optimize the time. Teams of engineers will study building by building, and their data can be used to check some cases, if necessary.

When dealing with a small settlement (village or a fraction of the village) it is more or less simple to go around and see all the buildings. When dealing with a larger settlement, it is

reasonable to divide it into parts and assign several teams to do the job block by block. All the collected data should be geo-referenced in situ, if possible; backup copies of photographs, videos and files produced during the field work should be made at least once a day. To be safe, it is good to have the ability to email or ftp the data regularly to another location, to prevent losses.

While entering areas with high intensity effects, team members must wear safety gear and be aware of the danger. In many cases a special permit should be obtained from the civil authorities, who then assign specialists (firemen, policemen, soldiers etc) to accompany teams and take care of safety issues. One should not underestimate the danger of aftershocks and additional collapses they might cause. The safety of the team members comes above the data. In case of two or more field investigation teams working in the same area, one should as much as possible liaise with these, with a view to avoiding duplication of effort and sharing experience.

As a general rule, one should also be careful to maintain good relations with the local community in the area being investigated. In areas that have suffered a major earthquake, residents may still be traumatised or shocked, and one needs to deal with them with tact and care. Even in cases of low-intensity earthquakes, one should take care to respect local cultural conventions (e.g. with respect to appropriate clothing).

#### **12.3.4.5 Later (post-earthquake) activities**

On return to base team members should take care to label carefully and archive all the collected data; all photographs, videos and other material should have in titles or captions clear data about the place where they were taken, names of the streets, buildings etc. All the data should be copied several times and stored in different archives, to prevent losses. It may be appropriate to continue liaison with other groups involved with the earthquake with a view to pooling and sharing data and experience.

### **12.4 Processing of macroseismic data**

The way in which intensity is assessed varies enormously according to whether one is proceeding from traditional paper questionnaires, in which case the process is essentially a subjective matching of the data to descriptions in the scale, or whether one is using an automatic algorithm to process data from the internet. These will be discussed separately. Field observation data can be considered “traditional” in this respect.

#### **12.4.1 Traditional intensity assessment**

Although the conversion of descriptive information to numerical intensity data by use of an intensity scale is fundamental to macroseismic studies, the process was in general rather poorly documented in the past. This led to considerable variations in practice from worker to worker, resulting in serious inconsistencies in results. It is widely recognised that assessing intensity in the traditional way is to some extent a subjective exercise, and that some variations between workers will always occur, but it is better if these are minimised through common methodology as much as possible.

The following points apply to most common intensity scales:

- Data should be grouped by place prior to assessing intensity. By "place" is meant a village or town or part of a city. Places should not be too big (like a county) or too small (like a single house). When assessing intensity for a place, all the data relating to that place should be considered together. If there are fifteen reports from one village, a single intensity should be assigned to those fifteen jointly, rather than making fifteen assessments and combining them. It is common for intensity scales to use phrases like "in many cases", or "in few cases", and this cannot be assessed on the basis of one questionnaire, hence the need to combine them.
- Make sure there are sufficient data for a reasonable assessment. If there are too few reports, or the reports are too lacking in detail, it is better to record merely that the earthquake was felt rather than forcing an intensity value on inadequate data. In some cases it will be possible to make a range assessment, e.g. 4-5, >6, (4 or 5, more than 6) etc. A single report may be very unrepresentative of the general experience.
- For each place, compare the picture of earthquake effects provided by the data with the idealised pictures provided by each description of an intensity degree in the intensity scale, in order to look for the best overall fit. The match will seldom be perfect, so it is necessary to look for the most coherent, general comparison. It should be remembered that given the very variable nature of intensity, in any place individual effects may be observed that are higher or lower than those to be expected from the general (modal) intensity level. It is important not to give these too much attention. For example, if most of the data for a place are suggesting intensity 4, but there is a single exceptional report that a chimney fell, this chimney does not invalidate an assessment of intensity 4 for the place.
- When using a quantitative intensity scale (MSK, EMS) then the comparison of the data with the scale will usually be a question of making a best fit of the percentages of a particular observation that were recorded and the percentage ranges expected for each degree of the scale. For EMS-98, the procedures for assessing intensity are discussed in detail in the scale support material (Grünthal 1998).
- The absence of reports of a particular phenomenon may or may not be evidence that it did not occur, depending on the nature and quality of the data. It cannot automatically be inferred that, for instance, an absence of reports of damage indicates no damage occurred, although this will often be the case. A positive statement along the lines of "there was no damage" is more reliable.
- To make inferences from a particular source of data requires an understanding of the nature and limitations of that data source. For instance, newspapers often pluralise things for effect, so a newspaper report that says "pictures fell from walls" may mean one picture fell from one wall. Where the sources are historical documents the advice of a professional historian in understanding the nature of the documents should be taken.
- Effects on nature (landslides, ground water changes, etc) should only be used with caution, since their frequency is strongly influenced by local hydrological conditions and other factors not related to intensity. It is therefore very difficult to arrive at reliable intensity values for remote, largely uninhabited, rural areas. (This point has been found unpalatable by some, but unfortunately is realistic).

#### **12.4.2 Automatic intensity assessment**

The collection of macroseismic data rapidly from internet questionnaires lends itself to automatic data processing. If intensity can be assigned algorithmically, the results of the

macroseismic survey can be continually updated and displayed in real time, a huge advantage. This also does away with any subjectivity in assessment, since the results are defined in terms of the algorithm, and are totally objective. The downside is that the correspondence between the algorithm and the actual intensity scale that it is intended to mimic is uncertain.

There are several systems in current use, but all can be divided into one of two approaches: those based on regression, and those based on an expert-systems approach.

The regression approach is typified by the “DYFI?” system, the basis of which is fully described in Wald et al (1999). In this system, each questionnaire is assessed as it is received, and scores are given based on answers to key questions. For each location from which responses are received, the scores from each question are tallied. The final score for the location is the weighted sum of the average scores for each question.

When the system was set up, a training set was compiled of scores for a set of locations, together with human-assigned intensities for those locations. From that training set, a regression equation was developed between location score and intensity (Figure 12.3). For a current earthquake, this equation gives the intensity for any location by simply converting the final score value, or “community weighted sum” (CWS). Intensity is calculated from the CWS according to the equation

$$I = 3.4 \ln \text{CWS} - 4.38 \quad (12.1)$$

This allows decimal intensities, in that, for instance, a CWS of 15 gives an intensity of 4.8 MM – but this should be tempered by the standard error of equation (12.1), which is unfortunately not given by Wald et al. (1999), but appears by eye to be between  $\pm 0.5$  and  $\pm 1.0$  degrees. The lower the CWS the greater the scatter in the regression, though this is probably mainly due to poorly constrained values in the training data set. The inherent uncertainty in computed values is uncertain, but likely to be higher for locations with few questionnaires.

**Fig. 12.3** Regression of community weighted sum against intensity; reproduced from Figure 1 in Wald et al. (1999). NR = Northridge, WN = Whittier Narrows, SM = Sierra Madre. For further information, see the original paper.

The system does not impose a minimum number of questionnaires before assigning an intensity, but the number received may be useful supplementary information in estimating uncertainty.

The expert systems approach is quite different, and seeks to emulate the thought processes of a seismologist using an intensity scale in the traditional way. Such a system is described by Musson (2006) for the EMS-98 scale. The basis of it is an assessment of the totality of reports received from a location compared to the requirements of the scale. For this purpose, for key effects, the proportion of observers at a location who reported the effect is computed. This might be, for instance, that 35% of questionnaires from a place answered yes to “did windows or doors rattle?”. Such ratios cannot meaningfully be established from single or very few questionnaires, so for places with very few replies, only “felt” will be returned.

Once the ratios have been computed, the effects at each place are considered by a process of elimination. This runs as follows:

- First, was the earthquake felt at all? If all the reports are negative, the intensity is 1 EMS and processing stops. Second, are there many reports of substantial damage? If so, the intensity is 7 or 8 EMS (8 being the upper limit of the system) and more detailed tests are applied to choose which.
- If the intensity was not 1, 7 or 8, the next thing to look at is whether there is a high proportion of “strong” effects like objects falling, people running out, minor damage, and so on. If this is the case, the intensity is 5 or 6 EMS and more detailed tests are applied to choose which. If this is not the case, only intensities 2, 3 and 4 are left. If the preponderance of data suggests that many or most people felt the earthquake and there were some physical manifestations like rattling doors, the intensity is assessed as 4 EMS. If it is found that only people at rest on upper floors felt it, the intensity is 2 EMS. If neither of these is the case, the intensity is finally 3 EMS.

Both approaches have positive and negative features. Regression-based systems can be calibrated to past national data sets to maintain consistency; but they then inherit whatever subjective practices informed the intensity assessments of the calibration data set. The expert systems approach, in contrast, is tied to the interpretation of the actual intensity scale, and not any previous data sets (and therefore may not be precisely compatible with them).

The regression approach will always return a numerical intensity, where the expert systems approach will not. On the other hand, the uncertainty in intensity estimates from a regression-based system may be large, especially if based on few questionnaires. The expert systems approach effectively redefines the scale as a series of specific tests, from which it follows that there is no uncertainty at all in any assigned intensity value – at least, with respect to the data on which the assignment is made.

In both approaches, there is still the problem that a self-selected sample from a large population (the total number of inhabitants of the location) is likely to be unrepresentative. Therefore, besides any inherent uncertainty in assessment, there is an additional unquantifiable uncertainty as to the relation between the sample (the questionnaires received) and the total population.

Note that this uncertainty would be quantifiable if the sample was randomly drawn from the population, instead of being self-selecting. As well as a probable bias towards positive

responses, there may also be a demographic bias, in that some categories of people are less likely to be internet users. These people are also likely to live in poorer housing, and there may in some cases be other influences on the data, for example in places where wealthy suburbs are built on high ground and poorer suburbs on reclaimed land.

More details on these two systems, and the actual software required to implement them, are available from USGS and BGS respectively, on request.

### **12.4.3 Accuracy of assessment**

The previous paragraphs lead naturally into a consideration of what degree of accuracy in intensity assessment can be expected in general.

Given a certain strength of shaking, it is to be expected that buildings of equivalent strength will not respond in a completely uniform way. Rather, there should be a modal level of damage observed, with some buildings suffering less and others more. The net effect approximates to a normal distribution (as has often been seen in damage surveys). Thus, for any particular level of shaking, it is expected to be found that different percentages of the building stock of a given strength will suffer different degrees of damage. In assessing intensity (and this is true of the lower degrees as well as the damaging ones) one is usually dealing with a sample or estimate of the percentages that were observed, and attempting to match these to the expected ranges for one of the intensity degrees. In most cases, given a degree of robustness, an adequate fit can be found without much problem.

Difficulties can occasionally arise when this task is compounded, as it sometimes is, by one or other of two factors: (i) that the effects of an earthquake vary considerably over very short distances, due to a combination of local conditions and the complexity of earthquake ground motion; and (ii) information is often not complete. These two factors can have an effect on the level of accuracy that can be expected in intensity assessments. The variability of earthquake effects is well-known, as in cases where, of two identical houses side-by-side, one is heavily damaged and the other nearly intact. This may give a misleading impression of difficulty in assessing intensity which might actually disappear once a larger sample of houses was assessed. The difficulty with respect to information is that one is often working from an uncontrolled, possibly unrepresentative, sample of the whole data population (particularly when not working with data derived from a field investigation), and there may also be uncertainty about the condition of buildings before the earthquake. This can cause problems where the real percentage distribution of effects is obscured by the limited data. Also, even when the amount of data is good, there can be cases where the reported effects do not match unambiguously any of the "pen pictures" presented by the classes in the intensity scale.

In cases where one cannot determine intensities to a resolution of one degree, two degrees can be bracketed together to show the probable range. This can be particularly the case for lower intensity degrees; there are often cases where it is hard to be sure between intensity 2 or 3, or between 3 or 4, or between 4 and 5. In such cases one may write 4-5, meaning either intensity 4 or intensity 5.

One guideline that can be suggested is that the description of each degree should be considered the minimum case. For example, in a case in which the data satisfy the requirements for intensity 4, but certainly do not adequately satisfy the criteria for intensity 5,

then the correct assessment is 4, even if the effects seem stronger than the basic intensity 4 description.

Intensity scales are designed to include the necessary degree of robustness to make identification of the different degrees as practical as possible. The number of degrees in a scale is controlled by the number of different levels that can be distinguished in normal use without too much difficulty. Experience shows that it is very unlikely that one could ever meaningfully discriminate intensities to a resolution of less than one degree of a twelve-degree scale. If one could state accurately in some case that the intensity was, for example,  $6\frac{1}{2}$ , this would imply that a 23 degree intensity scale could be written, which is doubtful.

This reservation does not apply to algorithmically computed intensities; as shown above, a “DYFI?” intensity of 4.8 has a precise meaning – that the community weighted sum for the locality from the questionnaires received was 15. While it might not seem that “ $4.8 \pm 0.5$ ” is really more meaningful than “5” or even “4-5”, it is reported that the fractional intensities computed this way do tend to show a smooth attenuation with distance (Atkinson and Wald 2007).

It may be no coincidence that modern intensity scales are converging on ten degrees as the optimal amount of discretisation possible. The JMA scale, with its degree 0 and split 5 and 6 degrees has ten degrees in total, and the major twelve-degree scales are effectively ten-degree scales, since in modern practice, intensity 11 and 12 are not used. At very high intensities, scales tend to saturate once all buildings have been destroyed. In areas where the building stock is very poor, this can be as low as 8 or 9 MMI-MSK-EMS. EMS-98 attempts to discriminate intensities 11 and 12 by extrapolating damage distributions to building stock with modern anti-seismic design, but this is largely untested in practice. Some other scales define intensity 11 and 12 in terms of secondary effects that are actually due to surface faulting, slope failure or liquefaction, and are not truly indicators of intensity.

#### **12.4.4 Equivalence between scales**

The translation of values from one scale to another has been discussed in detail by Musson et al. (2010), whose conclusions can only be summarised here.

It has often been the practice to attempt to express the equivalence between different intensity scales by way of a chart that compares different degrees of a scale by a series of rectangles overlapping to a smaller or larger extent. Such charts are unhelpful, partly because they imply that, for instance, intensity 5 in one scale may be “slightly higher” than intensity 5 in another scale, when in integer degrees there is no “slightly higher”. Secondly, any set of intensities is a combination of the scale employed and the working practices used in the assessment. One worker may make the assumption that if there is any damage, the intensity must be at least 6, another worker may not, and the result will be consistent variation even if both are using the same intensity scale.

For practical purposes, therefore, it is much preferable to revisit the original data and make a fresh intensity assignment with the desired intensity scale. However, this may not always be possible.

Comparing the scales as written, rather than as used, Musson et al. (2010) found no significant differences between MM-56, MSK, MCS and EMS-98 This is in accord with the

table of equivalences by Shebalin in the original MSOP (Willmore 1979) for MM-56, MCS and MSK. It is noted though, that in practice, intensity data points assigned with MCS have a tendency to be higher than those assigned using other scales. The Stover and Coffman (1993) scale breaks the pattern slightly, since 1 MM-93 could be 1 or 2 EMS-98, and more importantly, 4 MM-93 could be 4 or 5 EMS-98.

The higher degrees of scales cannot really be compared because of saturation problems, as discussed above.

A rough equivalence for the JMA (2009) Scale is given in Tab. 12.1 below. This varies significantly from the table given in Musson et al. (2010), due to the changes made in the 2009 revision of the JMA scale, after Musson et al. (2010) was submitted.

**Tab. 12.1** Equivalence between JMA-09 and EMS-98 intensity values

| <i>JMA Scale</i> | <i>EMS-98</i> |
|------------------|---------------|
| 0                | 1             |
| 1                | 2             |
| 2                | 3             |
| 3                | 4             |
| 4                | 5             |
| 5 Lower          | 6             |
| 5 Upper          | 7             |
| 6 Lower          | 8             |
| 6 Upper          | 9             |
| 7                | 10            |

## 12.4.5 Presentation of intensity data

Practice in the earlier part of the 20<sup>th</sup> century was generally to publish intensity data in the form of an isoseismal map. An isoseismal can be defined as a line bounding the area within which the intensity is predominantly equal to, or greater than, a given value. No definitive method of contouring has ever been agreed. Some workers adopt a practice of overlaying a grid on the data and taking the modal value in each grid square prior to contouring, others prefer to work directly on the plotted intensity values. Workers have differing preferences for the amount of smoothing, extrapolation, etc, that is to be employed. Thus, the drawing of isoseismals has always been to some degree subjective.

While an isoseismal map often gives a good visual impression of the effects of an earthquake, and the areas within each isoseismal can be used for some purposes (e.g. estimation of focal depth; see 12.5.5.), such maps are inadequate for modern studies, partly due to the subjectivity problem, and partly because many applications of interest require point data (e.g. Bakun and Wentworth 1997, Gasperini et al. 1999, Musson and Jiménez 2008).

The primary requirement, therefore, is to publish the intensity data for any earthquake in the form of a table of intensity data points (IDPs), where each IDP has, as a minimum, latitude, longitude and intensity (using Arabic numerals, not Roman ones), and may also have locality name, some quality factor (for instance, the number of questionnaires contributing to the

assessment) and other metadata. Such publication is now sometimes done in the form of an online database, much to be encouraged – SISFRANCE (www.sisfrance.net) is an example (Fig. 12.4).

**Fig. 12.4** Screenshot from the SISFRANCE website, showing a macroseismic display of a Central Pyrenees earthquake from 2002.

Mapping of intensity data is now predominantly done by showing maps of the IDPs themselves. There are three principal ways of representing IDPs on a map. The simplest is to plot each intensity as a number. This works adequately if there are only a few well-spaced points to be displayed, but if the point density is high, the map quickly becomes hard to read. Also, such a map does not give a very clear visual impression of the overall intensity distribution. A better alternative is the set of international symbols (first introduced by KAPG, the Commission of the Academies of Sciences of Socialist Countries for Planetary Geophysical Research) based on colouring in different proportions of small circles (Fig. 12.5). This gives more of a visual impression, and can be used in monochrome figures. The KAPG

symbols are only really standard between intensities 2 and 8; outside this range they vary between different studies. Those shown in Fig. 12.5 are as used in Shebalin (1973).

With colour printing becoming more accessible in journals, and straightforward in internet publication, the most common system now is to use coloured dots for IDPs. While there is no single standard colour scale, the norm is to use a colour spectrum such that low intensities use blues and greens, middling ones use yellow and orange, and higher ones use reds, browns, purples and black. Fig. 12.5 shows such a scheme, devised for the Archive of Historical Earthquake Data (AHEAD), produced by the NERIES project in Europe (see <http://www.emidius.eu/AHEAD/>), which includes a convention for uncertain values split over two degrees. In this system, “felt” is plotted as an empty green circle. Also shown is the colour scale for use with the DYFI? System. The SISFRANCE colour scheme is visible in Figure 12.4.

**Fig. 12.5** Three different systems for plotting intensity values; monochrome symbols and two approaches to using colour.

Isoseismal maps still have their uses. The degree of smoothing employed in their construction should reflect the purposes to which the resulting map will be put. If the map is intended for microzonation work, i.e. to point up areas where seismic hazard may be enhanced owing to local soil conditions, then smoothing will be at a minimum, and isoseismals will be as convoluted as the data. If the map is intended for other purposes (calculation of earthquake parameters, attenuation studies, tectonic studies, etc) then the curves will normally be smoothed so that only major re-entrants and outliers are shown. In practice, smoothed isoseismals are much more common. As a general rule, re-entrants and outliers should not be drawn unless suggested by a grouping of at least three data points. If isoseismals have to be interpolated or extrapolated across areas of water, or areas without data points, these sections of the lines should be shown as dashed. In cases where, for example, an epicentre is offshore, and only (say) a 120° arc of each isoseismal would fall onshore, it is not correct to project the whole of the remaining 240° of each isoseismal on a map, even as a dotted line. Only the

onshore section should be drawn, with each line tailing off with a short dotted section offshore if desired. Plotting isoseismals that are completely offshore and merely projections of an intensity attenuation curve should not be done. For onshore earthquakes with few data, it is not good practice to attempt to draw isoseismals conjectured from one or two points only; at least three mutually supporting data points for one intensity value should exist before one attempts to draw even a partial isoseismal for that value. Figure 12.6 shows some examples of acceptable and unacceptable drawing of isoseismals.

**Fig. 12.6** Two examples each of acceptable (upper row) and unacceptable practice (lower row) in drawing isoseismals.

Computer contouring programs often do not give good results with macroseismic data, as too often parts of the macroseismic field are poorly constrained; though Schenková et al (2007) report good results from kriging (a linear least-squares method commonly used for interpolation of geospatial data in the earth sciences).

## 12.4.6 Exchange of macroseismic data

Earthquakes are obviously no respecters of international boundaries, and it is not uncommon for the felt area of a significant earthquake to extend into more than one country. In the case of the 1992 Roermond earthquake, macroseismic data was collected from the Netherlands, Germany, Belgium, Luxembourg, France, the UK, Switzerland and the Czech Republic (Haak et al 1995). Exchange of data is clearly important. However, problems can arise if what is exchanged is simply tables of IDPs, as these may be assessed using different scales or methods, and may not be compatible. Some means are necessary for exchanging data at a lower level – that of the original questionnaire, at least in some abstracted form. A format is needed that can provide a record for each questionnaire that includes, besides location, values representing the effects reported. The greater the degree of international standardisation of questionnaires, the easier such a format will be to construct, but clearly, it needs to represent a superset of the types of information collected by different questionnaires and used by different systems. At the time of writing, there are initiatives to develop such a format in the scope of QuakeML (<https://quake.ethz.ch/quakeml/QuakeML>).

## 12.5 Determination of earthquake parameters from macroseismic data

The determination of earthquake parameters (principally epicentre and magnitude, also depth in some cases) from macroseismic data is of critical importance for historical seismology, where it is the only way in which one can assess earthquakes of the pre-instrumental period. For observatory practice, these parameters will of course be determined from instrumental data, but it can be instructive to compute the macroseismic equivalents as well, partly as a means of checking how a recent earthquake would appear in the catalogue had it occurred before 1900. The highest intensities may in some cases be some distance from the instrumentally-determined epicentre (i.e. the point on the earth's surface above the focus of the earthquake where the rupture initiated).

There is also one purely macroseismic parameter, epicentral intensity (and its close relation, maximum intensity) to be considered.

### 12.5.1 Epicentral intensity

Epicentral intensity, usually abbreviated  $I_0$ , is a parameter commonly used in earthquake catalogues but rarely defined, and it is clear that different usages exist in practice (Cecić et al 1996). The meaning of the term is clearly the intensity at the epicentre of the earthquake, but since it is likely that there will not be observations exactly at the epicentre itself, some way of deriving this value is necessary. The two main techniques that have been used in the past are:

1. Extrapolation from the nearest observed intensity data to the epicentre without changing the value, or use of the value of the highest isoseismal. Thus if there are a few data points of intensity 9 near the epicentre, the  $I_0$  value is also 9. If the epicentre is significantly offshore,  $I_0$  cannot be determined.
2. Calculating a fractional intensity at the epicentre from the attenuation over the macroseismic field, using a formula such as that by Blake (1941) or Kövesligethy (1906).

In this case, because this is not an observed value (and not a "true" intensity) it may be expressed as a decimal fraction without contravening the rule that intensity values are integer.

It is recommended that these two methods be discriminated between by the notation used. Thus an integer number (9 or IX) indicates method (1) and a decimal number (9.0 or 9.3) indicates method (2). It is recommended that one should not add arbitrary values to the maximum observed intensity when deriving an  $I_0$  value; the arbitrary amount is too subjective.

As well as epicentral intensity, a useful parameter is maximum intensity, abbreviated  $I_{\max}$ . This is simply the highest observed intensity value anywhere in the macroseismic field. For onshore earthquakes,  $I_0$  and  $I_{\max}$  may be equal. For offshore earthquakes it is often not possible to estimate  $I_0$  (especially if method 1 is used), but  $I_{\max}$  can be given for any earthquake.

### 12.5.2 IDPs and isoseismals

There are two basic strategies in determining parameters from macroseismic data – to work with the raw IDPs, or to draw isoseismals and work with those.

The reason for using isoseismals is this: they can reduce or eliminate effects due to population distribution. Consider Fig. 12.7, in which an earthquake produces its highest intensities at several places on the mainland and in one island location. A seismologist, knowing that the irregular distribution is due to topography, might estimate an isoseismal as shown, which might be a better expression of reality than that obtained from processing of the individual data points, in which the clustering due to population factors has an influence. From an isoseismal one could deduce an epicentre in the position of the solid star; from data points one would be likely to obtain the position of the open star.

**Fig. 12.7** Illustration of different macroseismic epicentres obtained from (a) intensity 6 data points (open star) and (b) a possible interpretation of isoseismal 6 (solid star).

However, because of the subjectivity in isoseismal construction, modern opinion favours the direct use of the IDP distribution, without any isoseismals. Currently three systems are available for the computation of the main earthquake parameters from IDP sets. These are the Bakun-Wentworth (B-W) method (Bakun and Wentworth 1997), the BOXER method (Gasperini et al. 1999) and MEEP (Macroseismic Estimation of Earthquake Parameters, Musson and Jiménez 2008). These will be discussed further in the next sections. Fig. 12.8 shows a comparison of results from the three methods for a sample earthquake. In this case, the parameters obtained can be compared to instrumental values; for historical earthquakes it can be the case that location methods disagree with no clear indication which is more reliable.

**Fig. 12.8** Comparison of macroseismic parameter estimations for a British earthquake, together with the instrumental parameters.

### 12.5.3 Macroseismic epicentre

Macroseismic epicentre is an expression which has been used in the past to convey different concepts, never properly defined. On the one hand, the macroseismic epicentre can be considered to be the best estimate made of the position of the epicentre without using instrumental data. This may be derived from any or all of the following circumstances dictate: position of highest intensities, shape of isoseismals, location of reports of foreshocks

or aftershocks, calculations based on distribution of intensity points, local geological knowledge, analogical comparisons with other earthquakes, and so on. This is a rather judgmental process with some subjectivity, and does not lend itself to simple guidelines that can be applied uniformly in all cases.

More commonly, the term is used for the point on the Earth's surface from which the macroseismic field appears to radiate. In the past this was often the centre of the highest isoseismal or the weighted centre of the two highest isoseismals. The terms “barycentre” “intensity centre”, “macrocentre” and “macroseismic centre” have been proposed as alternative terms.

These two points are often the same, but need not be. For any study of the tectonics of an area, the macroseismic epicentre is perhaps more useful. For studies of seismic hazard, especially those using a technique like extreme value statistics, the barycentre gives a better indication of the hazard potential of an earthquake.

The BOXER method computes epicentres by taking the trimmed mean of the latitudes and longitudes of the highest intensity locations (using also the second-highest values if there are insufficient points otherwise). It also computes an estimate of the rupture dimensions of the fault; this is the only method that handles extended sources from IDP data.

The B-W and MEEP procedures both work on the basis of attempting to minimise residuals from a theoretical intensity distribution that can be derived from some attenuation model, a procedure first proposed by Perruzza (1992). In the case of the B-W method, the model used is of the type expressing intensity as a function of magnitude and distance. In MEEP, the model used is one expressing the reduction of intensity from the  $I_0$  value as a function of distance. In both cases, a grid search is used to locate the position at which the misfit between the best set of predicted values and the actual values is minimised. Both these methods are capable of locating earthquakes offshore, which BOXER generally cannot do. However, especially with poor data sets, they can get trapped in false minima.

#### 12.5.4 Macroseismic magnitude

The use of macroseismic data can give surprisingly robust measures of earthquake magnitude. Early studies attempted to correlate epicentral intensity with magnitude; however, epicentral intensity can be affected by focal depth or soil amplification, so such simple correlations may perform poorly.

The total felt area ( $A$ ) of an earthquake, or the area enclosed by one of the outer isoseismals (usually 3 or 4), tend to be a better indicator of magnitude, being not much affected by depth (except in the case of truly deep earthquakes) or soil conditions, and since the relationship between the area and magnitude is logarithmic, even a substantial mis-estimation of the total felt area will not produce an overly large error in the magnitude. For earthquakes below a threshold magnitude (about 5.5 Mw) magnitude and log felt area scale more or less linearly, and so equations of the form

$$M = a \log A + b \quad (12.2)$$

can be established regionally by examination of data for earthquakes for which macroseismic data and instrumental magnitude are both available. For larger earthquakes, differences in

spectral content may affect the way in which earthquake vibration is perceived, and a different scaling appears to apply. In Frankel (1994) the form

$$M = n \log (A / \pi) + (2 m / (2.3 \sqrt{\pi})) \sqrt{A} + a \quad (12.3)$$

is used to represent the full magnitude range, where  $n$  is the exponent of geometrical spreading,  $a$  is a constant, and

$$m = (\pi f)/(Q \beta) \quad (12.4)$$

where  $f$  is the predominant frequency of earthquake motion at the limit of the felt area (probably 2-4 Hz),  $Q$  is shear wave attenuation quality factor and  $\beta$  is shear wave velocity (3.5 km/sec). Using this functional form and comparing world-wide intraplate earthquakes with interplate earthquakes from one region (California), Frankel found the difference in magnitude for the same felt area to be on average 1.1 units greater for California.

In the above equations,  $M$  has been used for generic magnitude; for any particular magnitude equation it is important to specify what magnitude type the derived values are compatible with ( $M_s$ ,  $M_L$ ,  $M_w$  etc). It is also useful to determine the standard error, which will give a measure of the uncertainty attached to estimated magnitude values.

Magnitudes calculated by BOXER adapt a model proposed by Sibol et al. (1987):

$$M = a + b I_o^2 + c \log^2 (A_I). \quad (12.5)$$

Here  $A_I$  is the area of each intensity  $I$ , calculated from the median distance of IDPs of value  $I$ . The formula is applied for each intensity in the data set, and the magnitude is given by the weighted average.

For the B-W method, since it is based on the optimisation of a model including magnitude, the optimal magnitude is a by-product of the location procedure.

MEEP adapts the Frankel model given above to estimate the limit of intensity 3 for a hypothetical magnitude. The radii of higher “isoseismals” are then interpolated and compared to the data to find the optimal magnitude.

Common to all methods is the need to perform a regional calibration before magnitude can be calculated from intensity data, something not needed for computation of epicentres.

## 12.5.5 Estimation of focal depth

The estimation of focal depth from macroseismic data was first developed by Radó Kövesligethy. His first paper on the subject presented the formula

$$I - I_o = 3 \log \sin e - 3 \alpha (r/K) (1 - \sin e) \quad (12.6)$$

where  $\sin e = h / r$  ( $h$  is depth,  $r$  is isoseismal radius) and  $K$  is the radius of the earth, and  $\alpha$  is a constant representing anelastic attenuation (Kövesligethy 1906). A second paper, (Kövesligethy 1907) contains a different equation:

$$I - I_0 = 3 \log \sin \varphi \quad (12.7)$$

where  $\varphi$  is the angle of emergence. Why the absorption term was dropped in this publication is unclear. Equation 12.6 was subsequently rewritten and modified slightly by János (1907), to reach the now well-known formula

$$I_0 - I_i = 3 \log (r / h) + 3 \alpha m (r - h) \quad (12.8)$$

where  $r$  is the radius of the isoseismal of intensity  $I_i$  and  $m = \log e$  (Euler's constant). This work was developed further by Blake (1941) whose contribution was essentially a reduction and simplification of equation (12.8); Blake's version is still used by some workers today, but Kövesligethy's original equation (in János's version) is more commonly encountered. Kövesligethy's equation became more widely known, in the form of equation (12.8), through the work of Sponheuer (1960). However, although Sponheuer references Kövesligethy (1906) in his text, he cited Kövesligethy (1907) in the reference list, and the relative inaccessibility of these papers, and this misreference, has caused some confusion which it has only recently been possible to unravel. A further puzzle is that János (1907) attributes equation to (12.8) to Cancani, transmitted by Kövesligethy; the involvement of Cancani in this is unclear (Zsiros 1999, pers. comm.).

The constant value of 3 used in equations 12.6 - 12.8 represents an equivalence value between the degrees of the intensity scale and ground motion amplitudes. This may vary regionally, and can be optimised (Levret et al 1996). The attenuation parameter  $\alpha$  should be determined regionally by group optimisation on an appropriate data set - not for individual earthquakes; some proposed values for different parts of Europe are given in Karník (1969).

$I_0$  here is an interpolated value, not the highest observed integer value, and has to be solved for as well as solving for  $h$ . This can be done graphically - one can fit the isoseismal data to all possible values of  $h$  and  $I_0$  and find a minimum error value consistent with the observed maximum intensity (e.g. Burton et al 1985, Musson 1996).

Macroseismic depth determination has attracted less interest than epicentre and magnitude, partly because for large earthquakes, focal depth is not of great practical importance. While the application of equation (12.8) can give quite good results for small crustal earthquakes, irregular data sets have a tendency to depress the depth estimate to the maximum allowed, and this is probably a worse problem when using IDPs rather than isoseismals. Of the three recent analysis methods from IDPs, MEEP is the only one that supports depth determination, using equation (12.8).

## 12.5.6 Intensity attenuation

Intensity attenuation, the rate of decay of shaking with distance from the epicentre, can be expressed in two ways. Firstly, there is the drop in intensity with respect to the epicentral intensity. This is shown by the Kövesligethy (1906) formula in equation (12.8).

It is generally more useful to express intensity attenuation as a function of magnitude and distance. Such formulae often have the functional form

$$I = a + b M + c \log R + d R \quad (12.9)$$

where  $R$  is hypocentral distance, and  $a$ ,  $b$ ,  $c$  and  $d$  are constants. (The last term is sometimes dropped, especially in intraplate areas). Since most earthquake catalogues include magnitude as a parameter, this form of intensity attenuation is extremely useful in seismic hazard studies. This type of model is also that required by the Bakun-Wentworth method described above.

A particular use of this type of model is in estimating the expected impact of an earthquake that has just occurred. Since a magnitude will be available at once, an equation of the form of (12.9) can give an immediate idea of how far the earthquake will be felt.

## Acknowledgments

The first author would like to thank the numerous people who made comments on the original text and suggested improvements; particularly Gottfried Grünthal and Tibor Zsiros. I am also appreciative of the support from members and associates of the NERIES-NA4 project, especially Bill Bakun, Antonio Gomez Capera, Paolo Gasperini, Maria-José Jiménez, Carlo Meletti and Max Stucchi. Thanks also to Jim Dewey of USGS and Maria-José Jiménez of CSIC for reviewing the final text; and also to Susanne Sargeant of BGS. This contribution is published with the permission of the Director of the British Geological Survey (NERC).

## 13.1 Introduction

Volcanic eruptions and their impact on human society, following earthquakes and meteorological disasters, are the most severe natural hazards. Since the pioneering works of Omori (1911), Sassa (1936) and Imbo (1954), much attention was focused on the seismic signals preceding or accompanying a volcanic eruption. Soon after the start of more extensive seismic monitoring it became clear that volcanoes show a variety of different seismic signals, which often differ from those produced by common tectonic earthquake sources, i.e., double couple type sources.

Starting with the availability of small portable seismographs in the late 1960's to early 1970's, a tremendous number of observations were made at different volcanoes and during different stages of activity. At the same time, first attempts were made to explain some of the seismic signals recorded and to classify the different signals by their proposed (but still mostly unknown) source mechanisms. Following this very enthusiastic period the progress in the study of accelerated magma transport to the surface was stagnating. Too many open questions remained unsolved, such as the mostly unknown source mechanisms of volcanic signals, the influence of the topography of volcanoes, the problem of proper hypocenter determination, the relationship between the occurrence of seismic signals of different type and the associated surface activity of a volcano. Since the late 1980's to early 1990's the use of portable and robust broadband seismometers and newly developed low power consuming 24bit A/D converters as well as the extensive use of seismic array techniques opened new horizons and different views onto the source mechanisms and the importance of volcano-seismic signals in the framework of early warning.

This chapter should be seen as a guideline for establishing a seismic monitoring network or at least a temporary experiment at an active volcano. Because of the large number of different volcanoes and many different kinds of source mechanisms, which may produce seismic signals, a description of all aspects is not possible. Also, a comprehensive review of case studies, including the variety of volcanic earthquake sequences, is beyond the scope of this paper. Relevant references include the excellent text books *Encyclopedia of Volcanoes* (Sigurdsson, 2000), *Monitoring and Mitigation of Volcano Hazards* (Scarpa and Tilling, 1996) and the comprehensive article of McNutt (2005). Most of the relevant topics dealt with in these text books are summarized below.

### **13.1.1 Why a different chapter?**

Volcano seismology uses many terms and methods known in earthquake seismology. This is no surprise as the same instruments and the same mechanism of elastic wave propagation through the Earth are used to investigate the subsurface structure and the activity state of a volcano. However, there are some deviations from conventional earthquake seismology, both in the physics of the signals and the methods of analyzing them. As outlined below, the signals vary from “earthquake-like” transients to long-lasting and continuous “tremor” signals. The most striking differences between earthquake and volcano seismology are the proposed source mechanisms and the related analysis techniques. In Section 13.2 and Section 13.4 we will discuss some of these aspects.

When setting up an earthquake monitoring network an optimal station coverage is needed in order to locate the events precisely. Depending on the tasks of the network, at least some stations should be located as close as possible to the active volcanic area in order to model the related seismic source with sufficient accuracy and determine the source depth. Hence, we are looking for a site-distribution which optimizes the station coverage and minimizes the influence of shallow structure and topography of the Earth. In contrast, in volcano-seismology we are left with sometimes very rough topography and nearly unknown propagation and site properties of the medium. Some of these aspects will be discussed in Section 13.3 and Section 13.4.

### **13.1.2 Why use seismology when forecasting volcanic eruptions?**

The use of seismological observations in the monitoring and forecasting of volcanic eruptions is justified because nearly all seismically monitored volcanic eruptions have been accompanied by some sort of seismic anomaly. The Pinatubo 1991 (Pinatubo Volcano Observatory Team, 1991), the Hekla 2000 (<http://hraun.vedur.is/ja/englishweb/heklanews.html#strain>) and the 2010 Mt. Merapi eruption ([http://www.merapi.bgl.esdm.go.id/aktivitas\\_merapi.php?page=aktivitas-merapi&subpage=seismisitas](http://www.merapi.bgl.esdm.go.id/aktivitas_merapi.php?page=aktivitas-merapi&subpage=seismisitas)) are examples of successful long- and short-term eruption forecasts made by mainly seismic observations. For further case studies on volcanic “early warning” see the comprehensive articles by McNutt (1996, 2000a, 2000b).

While most of these “early warnings” were simply deduced by counting the number and type of volcanic events per hour or day or even better by monitoring their hypocenter distributions, the physical meaning of the different seismic events and their relationship to the fast ascending magma are not yet well understood. To give an example: increasing volcanic

tremor is always a sign of high volcanic activity, but although the occurrence of tremor will increase the alert level, its role for short-term prediction is still not known with sufficient precision because we do not know the related physical process of this signal (fluid flow; movement of magma, water and/or gas; crack extension etc.). Furthermore, how can we distinguish between an intrusion and a developing eruption, both of which generate a large number of seismic signals and often share similar characteristics?

The extensive use of seismic methods during the last decades also showed that using them alone will not help the improvement of our knowledge about the internal processes of rapid magma ascent. This will be discussed in more detail in subchapter Section 13.5. Planning a new monitoring network or a short-term seismic experiment, we must also keep in mind that every volcano has its own characteristics, both with respect to seismic signal generation and wave propagation effects.

### **13.1.3 Why is a revised version needed?**

Since the writing of the first version of this chapter in 2002, much has changed both in the understanding of volcano-induced seismic signals as well as regarding technical aspects in recording the associated signals. The most dramatic changes appeared in the interpretation of the source mechanisms and the propagation of seismic waves at active volcanoes. This increased knowledge is mainly attributed to the availability of efficient numerical algorithms for simulating the signal generation as well as seismic wave propagation in complex media and by the increasing amount of high performance, parallel computing facilities. Another rising field in interpretation of volcanic unrest can be seen in the increasing number of applications in the field of remote sensing.

Both topics are far too large to be covered in detail in this manual. Especially the high performance computing part requires a lot of investment, which will not easily be covered especially in countries with multiple natural hazards and often small national budget. Therefore we will only briefly discuss the most important outcome of this expensive modeling.

While leaving the classification part nearly untouched, most of the changes in the revised version will be made in the source model part of Section 13.2 and some newly introduced analysis techniques in Section 13.4. Another major change is made in Section 13.5 where other monitoring techniques than seismology are briefly discussed. Here much more emphasis is given to new but already quite well established remote and ground based techniques (e.g., P-InSAR; SO<sub>2</sub> remote sensing; infra-sound measurement etc.). We finalize the revision by describing new technical developments in communication technology and software, i.e., database management systems, which are now thought to be “state of the art”.

## **13.2 Classification and source models of volcano-seismic signals**

Most of the confusion in volcano seismology is caused by the huge number of different terms for classifying volcano-seismic events. While this is mainly caused by the imperfect knowledge about the source mechanisms, we will focus on the basic nomenclature widely used in the literature. Most of these terms simply describe the appearance and frequency content of the signal, while others imply a certain source mechanism. However, one should be

aware in both cases that the sources are often unknown and the propagation medium alters the shape and the spectral content of the signals significantly.

While pioneering work in classifying volcano-seismic signals was made by Shimozuru (1972) and Minakami (1974), most of the following discussion follows the work of McNutt (1996, 2000a) and Chouet (1996a). We will divide the known signals mainly into transient and continuous signals, even if some of these continuous signals reflect simply the superposition of discrete signals. We will also discuss, where appropriate and physically plausible, differences in the signal generation related to different types of magma (i.e., low/high viscous, gas rich/poor). In addition to the usual classification, “up-to-date” source models and interpretation of the occurrence of different signals will be given.

## 13.2.1 Transient volcano-seismic signals

### 13.2.1.1 Volcanic-Tectonic events (deep and shallow)

*Deep (below about 2 km) Volcanic-Tectonic* events (VT-A) manifest themselves by the clear onsets of P- and S-wave arrivals and their high frequency content ( $> 5\text{Hz}$ ). This leads also to the class name *high-frequency* event (HF) (Fig. 13.1).

**Fig. 13.1** VT-A type event recorded at Mt. Merapi, Indonesia. The impulsive P- and S-wave arrivals are clearly visible in this signal, as well as their high-frequency content and short signal duration. The given color coding, representing normalized amplitude spectral density, is valid for all following figures. Also the amplitudes of the corresponding amplitude-time representation are in arbitrary units and when given are normalized to the amplitude shown in this figure.

The name of this event type implies a well known source mechanism, namely a common shear failure caused by stress buildup and resulting in slip on a fault plane similar to a tectonic earthquake source. The only difference from the latter is the frequent occurrence of swarms of VT events, which do not follow the usual main-after-shock distribution (McNutt, 2000a) and are located within a volcanic edifice. An earthquake swarm is a sequence where the largest events are similar in size and not necessarily at the beginning of the sequence. The high frequencies and the impulsiveness of the P- and S-wave arrivals seems to be caused by low scattering due to the short travel path through high scattering regions and low attenuation.

In contrast, *shallow (above about 1-2 km) Volcanic-Tectonic* events (VT-B) show much more emergent P-wave onsets and sometimes it is even impossible to detect any clear S-wave arrival (Fig. 13.2). The spectral bands are shifted to lower frequencies (1-5 Hz). Both observations are thought to be caused by a shallow hypocenter location and therefore a larger amount of scattering during wave propagation, especially of higher frequencies.

**Fig. 13.2** **a)** Typical example of a VT-B type event recorded during a high activity phase at Mt. Merapi. Note that the overall frequency content is mainly between 1 – 10 Hz with a dominant frequency at roughly 3 Hz. **b)** zoomed-in version of all three components of the same event. Whereas the P-wave arrival is clearly visible, no clear S-wave arrival can be seen. The circle marks the wavelet that has the approximate S-wave travel time for the estimated source location.

**Fig. 13.3** Two different models describing the occurrence of VT –A/B events when a volcanic crisis is eminent. While some VT events are simply caused by reactivation of existing faults by the increasing stress due to magma ascent, the other possible mechanism is directly linked to the emplacement of the magma in the feeder system and the associated tensile faulting. In this picture the difference between VT-A and VT-B is simply their location with respect to a high scattering region.

#### *Source models and interpretation*

Recently, detailed studies showed that the sources of some VT events deviate significantly from that of a pure shear failure, but show some similarities with the later described *Low-Frequency* events. An indication for location-dependent waveform changes is shown in Fig. 13.4. While the borehole station shows a seismogram which is typical for a common double couple source, the station at the surface within a volcanic caldera shows no visible S-wave onset, a lower dominant frequency but a very long coda. However, even using very sophisticated Moment-Tensor inversion techniques, which includes 3D Greens function computation (see Section 13.4.5) it is still not possible to resolve the ambiguity in estimating the “true” source mechanism of this class of signals. While there is a general agreement that the dominant part of the source process can be modeled by a double couple (DC), the role and amount of non-DC contributions remains debatable. Several papers on the inversion of the seismic moment tensor showed a significant contribution of non-double couple parts (Dahm and Brandsdottir, 1997; Saraò et al., 2001). The reason for the imperfect inversion will be discussed in more detail in Section 13.4.5.

**Fig. 13.4** Comparison of vertical component seismograms recorded in a borehole with records from the two surface stations nearest the borehole at the volcanic area of Long Valley Caldera, California. (from: Prejean and Ellsworth, 2001)

The main benefit in recording and analyzing VT-type earthquakes originates from the assumption that rising magma is acting as an additional stress source. This additional stress possibly superimposed by a regional stress field either leads to tensile faulting when magma is breaking the host rock or to earthquakes on preexisting faults in the country rock as a reaction to additional stress (see Fig. 13.3). While the first is directly linked to rising magma, the second possibility is a more passive and blurred image of magma inflation. Roman et al. (2006) showed that estimating fault plane solutions (see Section 3.4 in Chapter 3) gives important information of the current state of an active volcano and might, under certain conditions, serve as an important early warning tool. In their work Roman et al. (2006) showed that deep VT-A type events at Montserrat indicate a changing pattern of the P- and T-axis before a new eruption cycle starts. In their study the authors used a simple fault plane solution program (FPFIT, Reasenber and Oppenheimer, 1985) and thus neglect a more realistic velocity and topography. The estimated pattern, however, is striking and while planning a surveillance procedure, fault plane solutions should be considered as an important indicator of changing volcanic activity.

Recently found evidence in laboratory experiments (Lavalee et al., 2008) and in field observations (Tuffen et al., 2003) point towards a source region, which lies in the rising magma itself. Depending on the applied strain rate viscous magma might change its rheologic behavior from visco-plastic to brittle. Within this model, tracking the sources of VT events makes a direct estimate of the fluid path and rate possible.

A very distinct feature of VT events is their swarm like occurrence. McNutt (2002) pointed out that the main duration of VT-swarms is about 5 days. At several volcanoes the VT-A and VT-B type events happen several days to weeks prior a volcanic eruption. Whatsoever, it must be emphasized that the majority of magma ascent events, which on one hand are accompanied also by VT events, results in intrusions and will, on the other hand, not be associated with any surface, i.e., eruptive activity. This ambiguity is one major source of misclassification of the current state of a volcano.

### 13.2.1.2 Low-Frequency events

*Low-Frequency* events (LF or Long Period - LP) usually show no S-wave arrivals but a very emergent signal onset (Fig. 13.5). The frequency content is mostly restricted to a narrow band between 0.2-10 Hz. In the still rare cases in which the location of LF sources are determined, they are often situated in the shallow part of the volcano ( $< 2$  km). Locations are deduced mainly by amplitude distance curves, from the rare hypocentral determinations using clear first onset recordings, and by semblance location techniques from particle motions recorded on a broad-band seismometer network (Kawakatsu et al., 2000). Some volcanoes (e.g., Kilauea) are known to produce deep (30-40 km) LF events (Aki and Koyanagi, 1981; Shaw and Chouet, 1991). Fig. 13.6 depicts different models to described two of the proposed source mechanisms of LP –events.

**Fig. 13.5** **a)** example of a LF-wave group recorded at Mt. Merapi. Clearly the dominant frequency is around 1 Hz. **b)** shows an example of a LF event recorded at two different sites located at Redoubt volcano, Alaska (courtesy of S. McNutt, Alaska Volcano Observatory; AVO). The spindle shaped signal is also known as Tornillo.

**Fig. 13.6** Two different models to describe two of the proposed source mechanisms of LP – events. While in deeper parts of the volcanic edifice an oscillating crack model is the most appropriate source model, the signature of LP events in shallower parts can be explained best by pressure disturbances, caused by an ascending gas bubble within a (moving) fluid.

#### *Source models and interpretation*

The associated source models of LP events range from an opening and resonating crack when the magma is ascending towards the surface (Chouet, 1996a) to the existence of pressure transients within the low viscous fluid-gas mixture causing resonance phenomena within the magma itself (Seidl et al., 1981 see Fig 13.6). Both models are able to explain large parts of the observed features in the time as well in the spectral domain but leave the physics and the trigger mechanism unresolved. Papers by James and others (2006, 2009) show that the source process of low frequency events within low viscous magma can be modeled by pressure transients within the magma caused by changing geometry of the dike system (Fig. 13.7). This pressure transient in turn can cause an oscillation in the fluid.

Neuberg et al. (2006) and Collier and Neuberg (2006) propose a very detailed source and trigger mechanism for low frequency events in a more viscous magma environment. These authors argue that most of the magma ascent happens aseismically up to a certain depth level is reached where large portions of gas bubbles are formed. Within the magma column a strong gradient of viscosity is assumed, caused by the cooling of the outer layer of magma at the conduit wall. At a certain depth the transition from no slip to friction controlled slip occurs when reaching the brittle failure condition (Dingwell and Webb, 1990). After cracks and veins are created, gas can now escape and the ascent is then dominated by friction controlled slip which is aseismic (Collier and Neuberg, 2006).

**Fig. 13.7** Experimental setup and results of an ascending slug passing through a widening conduit. A clear pressure perturbation can be detected in the fluid and the accelerating slug may be also an effective mechanism for generating elastic waves in the surrounding subsurface structure (from: James et al., 2006).

An alternative mechanism for triggering LP or LF events is given by Denlinger and Hoblitt (1999). These authors favor a supply rate controlled stick-slip mechanism, which is deduced from observations of technical polymer melts. Both proposed trigger mechanisms are able to explain the frequently observed timely very regular repetition of LF events, which may lead even to a continuous signal (see Section 13.2.2.2). The model of Neuberg et al. (2006) and Collier and Neuberg (2006) is also able to explain the frequently observed similarity of waveforms in the recorded data. This is a surprising feature by its own as a volcano is a very heterogeneous geological structure making scattering distortion a very dominant feature. Numerical simulations by Sturton and Neuberg (2006) and Neuberg et al. (2000) show that the overall shape of the seismograms and their frequency content can simply be explained by the excitation of multiple reflected borehole (i.e., Stonely) waves at the magma-conduit interface.

In the context of using seismology as an early warning tool in volcanology the detection and analysis of LF/LP events is a very important tool, because of their direct connection to the ascending i.e. flowing magma within the subsurface. Monitoring fluid movement or pressure disturbance directly makes early warning much more successful and effective in both timing and size estimates of an eruption. However, there is still a large ambiguity caused by intrusion rather than extrusions, i.e. eruptions.

### 13.2.1.3 Hybrid events, Multi-Phases events

Some volcano-seismic signals share the signal and frequency characteristics of both LF and VT-(A,B) events. Signals of this class are usually labeled as *Hybrid* events, which may reflect a possible mixture of source mechanisms from both event types (see Fig. 13.8) and/or additionally reflect possible path effects (Harrington and Brodski, 2007). For example, a VT microearthquake may trigger a nearby LP event. Lahr et al. (1994) and Miller et al. (1998) detected swarms of *Hybrid* events during the high activity phase of Redoubt (Alaska) and Soufriere Hills volcano (Montserrat, West Indies), respectively. Miller et al. (1998) concluded that such events reflect very shallow activity associated with a growing dome.

**Fig. 13.8** **a)** shows a Hybrid event and **b)** a VT-B event for comparison. The higher frequencies at the beginning of the Hybrid event are an obvious feature, while the later part shows the similarity with the VT-B event (courtesy S. McNutt, AVO).

*Multi-Phase* events (MP also *Many-Phases* event; see Fig. 13.9; Shimozuru, 1972) are somewhat higher in their frequency content (3 to 8 Hz) than *Hybrid* events but are related as well to energetic dome growth at a very shallow level. The name reflect their complicated waveforms with seems to consist of multiple phases just after each other.

**Fig. 13.9** MP-event recorded at Mt. Merapi during strong dome formation. The frequency is restricted between 3 - 10 Hz and resembles that of a VT-B type event at this volcano. Note the long duration of this event whilst its amplitude is much smaller than for the VT-B event shown in Fig. 13.2.

### **Source models and Interpretation**

Both types of signals and their associated mechanisms are still a topic of research as their occurrence might be a good indicator for the instability and/or the growth rate of highly viscous lava domes. The trigger or source mechanism is likely the same for LP/LF events (see Section 13.2.1.2), while the source depth is significantly shallower at least in case of MP events. Recent advances in laboratory experiments, which investigate the plastic to brittle transition, point towards a source mechanism, which is located in the moving fluid itself (Lavallée et al., 2008).

#### **13.2.1.4 Explosion quakes, very-low-frequency events, ultra-low-frequency events**

Very pronounced *ultra long period* (ULP;  $f < 0.01\text{Hz}$ ) and *very low frequency* (VLF;  $f \sim 0.01 - 0.1\text{ Hz}$ ) signals are observed and are well documented at many volcanoes in Japan and on Hawaii (e.g., Aso: Kawakatsu et al., 2000; Iwate: Nishimura et al., 2000; Kilauea: Ohminato et al., 1998) using several broadband seismometers located in the near-field to intermediate-field distance from the source. To the same of class belong the *explosion quakes*, a signal that accompanies Strombolian or other (larger) explosive eruptions, showing clear waveform characteristics. Most of these signals can be identified by the occurrence of an air-wave which is caused by the sonic boom during an explosion, when the expanding gas is accelerated at the

vent exit (see Fig. 13.10, see also Section 13.5.1). This wave mainly travels through the air with the typical speed of sound (330 m/s at 20°C). While we do not discuss the explosive mechanism at the magma air interface in detail, the source, which leads to this explosion is not yet completely deciphered and several concurrent models will be discussed later. Some LF events show the same frequency-time behavior as the explosion quakes but lack an air phase (McNutt, 1986). This might reflect a common driving source of deeper LF-events and shallower explosion quakes.

**Fig. 13.10** An explosion signal recorded at Stromboli volcano, Italy. The seismic station was located just 400 m from the active vent. The dashed line gives a rough estimate of the onset of a sonic wave also visible as high (red) amplitudes in the time-frequency plot around 5 Hz.

Since the early 1990ies portable broadband seismometers with corner frequencies as low as 0.00833 Hz shed new light on this open question (see Fig. 13.11). It could be verified that at Stromboli volcano (Italy) ULF pressure buildup takes place several minutes before the onset of a Strombolian eruption (Dreier et al., 1994; Neuberg et al., 1994; Wassermann, 1997; Kirchdörfer, 1999). As this is only visible in the near-field of the seismic sources with a geometrical spreading factor proportional to  $r^{-2}$  (implying a simple volumetric source), the seismic stations must be located close to the active vent of the volcano (see Fig. 13.11). Since the first near-field broadband observations of strombolian activity many examples at volcanoes around the globe exist nowadays, making ULF signals a common signal accompanying low to medium viscous volcanism.

**Fig. 13.11** **a)** ULP signal recorded with a Streckeisen STS2 broadband seismometer at Stromboli volcano. We removed the instrument response down to 300 s and the resulting traces are integrated to reflect ground displacement. The three uppermost traces show the three-component seismograms of a station located 400 m from the vent, whereas the lower three traces show the same but at a site located 1800 m from the active vent indicating a large signal only visible in the near-field. The two circles mark two different types of seismic signals caused by strombolian activity which were not linked to different active craters. **b)** shows the seismogram of a 1 Hz seismometer during two different explosion quakes, the dashed lines mark the visible onset of strombolian eruptions. **c)** shows the displacement signal of two different explosion quakes. Note, not all explosion signals produce the same amount of long-period displacement signals.

**Fig. 13.12** a) ULP (or very long-period displacement) signal observed at three broadband stations during a phreatic eruption of Aso volcano. b) original velocity, band-pass filtered velocity and displacement seismogram of the same event observed at station TAK. The vertical line in b) indicates the onset of the eruption, all stations are located within 2 km from the volcanic centre (from: Kawakatsu et al., 2000).

ULF and VLF events are still unknown at most andesitic and rhyolitic volcanoes, which possibly implies that the described slug flow (Vergnolle and Jaupart, 1990, James et al. 2006) may be non-operative at this regime of viscosities. In contrast to this statement, the work of Hidayat et al. (2000) showed that there exists a moderate (0.25 Hz) VLF signal in the near-field of some MP events recorded at Mt. Merapi (Indonesia).

### Source models and Interpretation

Since the late 1980's to early 1990's many of the ULP-VLP observations were interpreted as shallow ( $z < 1.5$  km) phreatic eruptions with a strong low frequency pressure pulse ( $f \sim 0.01$  Hz; see Fig. 13.12). At Aso volcano Kawakatsu et al. (2000) also detected a second signal with dominant frequencies roughly at 0.06 Hz at the same depth range as the modeled phreatic source. The authors classified this signal as *long period tremor* (LPT), which is seen to reflect the merging of isolated pulses into a nearly continuous signal (see Fig. 13.13 and Section 13.2.2.2: Fig. 13.17). Kawakatsu et al. (2000) interpret these signals as caused by the interaction of hot magma/fluid with an aquifer situated in 1 - 1.5 km depth below the craters of Aso volcano.

**Fig. 13.13** Vertical component broadband seismograms band-pass filtered at 0.033 to 0.1 Hz at Aso volcano during three different days 1994. The isolated ULP pulses visible in a) and b) merge together in c) forming the continuous signal of *long period tremor* (from: Kawakatsu et al., 2000).

A different model of ULP/VLP generation, which fits the visual and seismological observations very well consists of a shallow magma chamber and a tiny feeder system to the surface, which may additionally vary in size and width. The accumulation of a gas pocket and the ascent of this pocket as a gas slug explain the observed pressure buildup up to a certain precision (Vergnolle and Jaupart, 1990). However, most of the strombolian eruptions at Stromboli and other volcanoes show only small over-pressure without any visible difference in the associated surface activity. Some more recent results of Gerst (2010) will be discussed in Section 13.5.1.

Results from still rare moment tensor inversion imply a rather complicated mixture of double couple (DC), compensated linear vector dipole (CLVD) and isotropic components (IC). In order to explain the recorded low frequency seismograms some authors combine a number of cracks, cylinders and additional single forces (Chouet et al., 2003; Cesca and Dahm, 2008; Aster et al., 2008; Chouet et al., 2010) for eruption at Kilauea (Hawaii) and Stromboli volcano or more violent explosions at Mt. Erebus (Antarctica). In Section 13.4.5 we will focus on the method of moment tensor inversion and its associated problems in much more detail.

A very comprehensive physical model for mild strombolian eruptions is given by a series of papers by James et al. (2006) and James et al. (2009). In these papers the physics of an ascending large gas pocket (slug) is experimentally and mathematically investigated.

The conceptional model of James et al. (2009) combines the viscous flow of the fluid film along the conduit wall and the pressure above in the fluid head (the nose) of a rising gas slug which is ascending in a volcano's conduit. This model is able to explain the change from gas puffing to strombolian eruption as well as the observed overpressures. The controlling factor between puffing and bursting is seen in the starting pressure, the length of the slug and therefore in the involved gas mass which is transported towards the surface (James et al., 2009). While this model can explain the observed infra-sound signals it will not explain the generation of LP/VLP/ULP signals during slug ascent.

In a different paper James et al. (2006) showed that changes in the conduit diameter can act as a very prominent source of pressure transients which then are able to couple into the surroundings and produce elastic deformation signals (Fig. 13.7). While models by Schick et al. (1982) and Seidl et al. (1981) in the early 80ies already describe similar mechanisms, the paper of James et al. (2004, 2006, 2009) put these ideas in the context of a physically and mathematically more quantitative model.

### **13.2.2 Continuous volcanic-seismic signals**

The appearance of continuous seismic signals at active volcanoes demonstrates the most profound difference between tectonic earthquake and volcano seismology. The suspected mechanisms range from obvious surface effects such as rockfall, landslide or pyroclastic density flow to internal ones such as volcanic tremor. Nearly every volcano world-wide shows the signal of volcanic tremor during different activity stages. Volcanic tremor is the most favored parameter in volcano early eruption warnings. Because of possibly differing source mechanisms we discuss tremor separately for the two flow regimes: high and low viscosity.

Recently the observation of so called non-volcanic tremor is attracting a lot attention in the seismologic community. This type of earth tremor is associated by slow, episodic slip in subduction zones, which makes it an important tool to understand the dynamical behavior of subduction related earthquakes. Sharing a lot of the signal characteristics with its volcanological counterpart, many of the methods developed in volcano-seismology are now further investigated in order to shed more light on this signal type.

### 13.2.2.1 Volcanic tremor (low-viscous two-phase flow and eruption tremor)

Most of the monitored basaltic volcanoes show some kind of cyclic appearance of *volcanic tremor*. The tremor signals can last between minutes and months in duration and, in most of the cases, their spectra are very narrow-band (1-5 Hz; Fig. 13.14).

**Fig. 13.14** **a)** explosion signals superimposed on the continuous signal of volcanic tremor at Stromboli volcano. The box marks the frequency band of a weak but typical volcanic tremor band at Stromboli volcano. Note that the explosion quake also excites the same frequency band whereas below this frequency band the spectral amplitude of the explosion quake type signals are somewhat smaller. The tremor band with frequencies above 2.0 Hz is partially distorted by the ejected volcanic debris falling back to the surface and tumbling down the slope of the volcanic edifice (see Section 13.2.2.3). **b)** the normalized Fourier transform of a explosion quake type signal (black) and of a normalized power spectrum of six hours of continuous recording (red). While the first reflects the typical spectrum of all explosion quakes, the overall behavior of the second spectrum is mainly due to volcanic tremor. The overall similarity between the explosion quake and tremor signal types is obvious.

Some tremor signals show strong and short-pulsed amplitude variations (termed *beating tremor*), while others are nearly stationary over several days or even months. The common similarities in the spectra of volcanic tremor and LF and even explosion quake events are another important observation which has to be explained when looking for the source mechanisms. At Mt. Etna volcano (Italy), strong fluctuations and changing signal characteristics of volcanic tremor amplitude are associated with lava fountaining at one of its summit craters or after the opening of a flank fissure (Cosentino et al., 1989, Langer et al., 2011). Gottschämmer (1999) described a tremor cycle at Bromo volcano (Indonesia) where the tremor amplitude fluctuation could be visually correlated with heavy ash plumes (large amplitude - *eruption tremor*) or white steam (small tremor amplitude) episodes (see Fig. 13.15).

**Fig. 13.15** Volcanic tremor at Bromo volcano (Indonesia) during a high activity phase at the end of 1995 (courtesy of E. Gottschämmer, University of Karlsruhe). Large tremor amplitudes correlate with the eruption of heavy ash plumes while small tremor amplitudes appear during quiet steam emissions (Gottschämmer, 1999).

These observations made at different volcanoes with either low viscosity magma or a huge amount of volatiles (free or after the fragmentation of high viscosity magma; steam) suggest the involvement of gas/fluid interaction in generation of volcanic tremor. In general it must be stated that the appearance of volcanic tremor is always a sign of high volcanic unrest, which might lead to an eruption. Whether this eruption may follow or the activity terminates by an intrusion cannot be decided without other geophysical/geodetical/geological evidences. Whatsoever, even in the cases where a well established and “complete” monitoring system exist signs of unrest or precursors may still carry significant ambiguities caused by the complexity of magma flow and the physics of volcanic eruptions.

### **Source models and Interpretation**

The similarities in the overall spectral content of LF/LP events and volcanic tremor are reflected in similarities of the proposed source mechanism or of the source region (resonating fluid). Flow instability is thought to play an important role in the excitation of volcanic tremor

in multiple phase flow pattern (Seidl et al., 1981; Schick, 1988; James et al., 2004, 2006) and the associated LF events are seen as a transient within the same physical system. On the other hand, Chouet (1987) and Chouet (1986) state that a repeated excitation of a connected crack system could cause a harmonic and long-lasting signal, where the fluid is only passively reacting to the crack oscillations. James et al. (2006) could show, that under certain circumstances the pressure transients produced by changing geometry of the feeder system can couple into the elastic solid surrounding of the feeder system (Fig. 13.7).

The spectral content observations support both the low viscosity magma and volatile interpretations. Explosions at Stromboli volcano excite the same frequency band as volcanic tremor does, which supports the idea of a common resonating system (Fig. 13.14). However, care must be taken when interpreting the frequency spectra of volcanic tremor. Detailed studies on the spatial frequency distributions at Stromboli showed that single frequency peaks are possibly influenced, to still an unknown amount, by the propagation medium (Mohnen and Schick, 1996).

### 13.2.2.2 Volcanic tremor (high-viscous - resonating gas phase)

During the last decade, many observations were made of the occurrence and characteristics of volcanic tremor at volcanoes with high-viscosity lava. At Semeru volcano (Indonesia) the spectra of volcanic tremor contained up to 12 overtones. This supports the assumption of a resonating medium with a high quality factor ( $Q$ ) as well as a precisely working feedback mechanism (Hellweg et al., 1994; Schlindwein et al., 1995) (Fig. 13.16). Similar observations were also made at Lascar volcano (Chile), where up to 30 overtones could be identified in the seismic signals (Hellweg, 1999).

**Fig. 13.16** Harmonic tremor signal recorded at Mt. Semeru, Indonesia. Up to six overtones can be recognized starting with a fundamental mode located at roughly 0.8 Hz.

### Source models and Interpretation

Schlindwein et al. (1995) proposed a feedback mechanism similar to that of sound generation in a recorder, and also discussed a repeating source with precise repetition time as a possible mechanism. This model was refined by Johnson and Lees (2000) and Neuberg et al. (2000). In the feedback mechanism case, the resonating body must consist of a pure gas phase as the lava at Mt. Semeru is too viscous for resonance at the observed frequencies. The second mechanism requires a very precise timing mechanism for producing the highly stable overtones. Observations at Montserrat volcano (Neuberg et al., 2000) and Mt. Merapi volcano (Indonesia) support the hypothesis of a repeating source (Fig. 13.17). During several cycles of increased volcano-seismic activity we recognized the transition from closely timed MP/Hybrid events into the continuous signal of volcanic tremor and vice versa. As the source mechanisms of both types of signals are still unknown, the driving force behind these mechanisms is also not known. Also the type of feedback mechanism, which needs to be involved in this model could not yet be identified.

**Fig. 13.17** Sequence of repeating seismic signals at Mt. Merapi volcano in 1996. a) very regularly timed MP-events before they merge together to form volcanic tremor (see b). c) after some hours the tremor is replaced by a sequence of discrete events with slightly higher amplitudes than before. Note: in contrast to the classification given in Fig. 13.5, the frequency content of these signals is lower (0.7 - 10 Hz) and might not resemble “pure” MP-events. In d) the marked time-frequency region of plots a)-c) are plotted in time domain. A band-pass between 0.8 - 1.3 Hz was applied before zooming. The individual wavegroups seen in the filtered continuous signal also supports the idea of the merged events causing the volcanic tremor.

Volcanic tremor is, as previously noted, always a sign of high activity. However, since the exact mechanisms are still unknown, the importance of and timing between the first appearance of tremor and possible eruptive activity is still a matter of discussion (McNutt, 2000a). The review papers by Konstantinou and Schlindwein (2002) and Kawakatsu and Yamamoto (2007) may give further information about the types and proposed source mechanisms of volcanic tremor.

### 13.2.2.3 Surface processes

Substantial release of seismic energy at active volcanoes is related to surface processes acting directly on the volcanoes edifice. For example, pyroclastic flows, lahars (volcanic debris flows) and rockfalls from unstable domes or crater walls can generate seismic signals with amplitudes exceeding several times those of the typical volcano-seismic signals. The most important signals for monitoring purposes are those associated with pyroclastic flows and lahars. The monitoring of lahars, which includes also acoustic and visual monitoring, is especially important when monitoring a volcano which is capped by a glacier or which is located in a tropical area. Melting the snow during an eruption or heavy rainfall during the rainy season will occasionally mobilize a huge amount of volcanic debris. The signals of all this activity are mostly high-frequency ( $>5$  Hz), show spindle (cigar) shaped seismogram envelopes that can last several minutes (Fig. 13.18).

**Fig. 13.18** Sequence of medium to larger pyroclastic flows recorded at Mt. Merapi volcano during the 1998 dome collapse. Note the 6-hour time scale and that individual events last many minutes, longer than the seismograms of typical earthquakes. Just before 4 hours the largest pyroclastic flow in the whole eruption sequence takes place and lasts for about 30 minutes.

### 13.2.3 Special note on noise

Most of the extensively monitored volcanoes lie in densely populated areas with strong human activity (that is why they are monitored). Hence, care must be taken when interpreting the signals usually classified as volcanic tremor. In some cases, human activity excites signals occupying the narrow spectral band between 1-4 Hz (big machines etc.). Also a distinct 24 h rhythm is very likely caused by increasing human activity during daylight time and should therefore be analyzed with special care (Fig. 13.19). Even when using three-component seismometers it is not easy to discriminate for sure between volcano-seismic and man-made noise. The topography at active volcanoes is very often radially shaped and the propagation paths to the seismic stations are shared by ambient seismic noise and volcanic signals.

**Fig. 13.19** Spectrogram of background noise recorded at a seismic station at Mt. Merapi. As the station is located in farming area, the human daylight activity can be clearly recognized by its distinct 24 hour periodicity. Furthermore, it is possible to see that there are two main working periods during daytime (marked by a box). Large spectral amplitudes are visible around 7 hrs local time and a second peak is located around 15 hrs after a time of quiescence during noon.

In conclusion, we note that most of the above classifications and proposed source mechanisms are deduced from simple observations of spectral content and overall shape of the associated seismograms rather than by physically verified constraints. Care must be taken when interpreting the occurrence of one of these signals during increasing volcanic activity. There are many examples of increasing numbers of VT events and increasing volcanic tremor amplitude without any surface activity at volcanoes. Thus, to be truly effective and diagnostic, seismic monitoring should be complemented, wherever possible, by other instrumental monitoring techniques (e.g., geodetic, geochemical) and regularly made visual observations of the volcanoes being monitored remotely (see Section 13.5).

## 13.3 Design of a monitoring network

One of the most important decisions to be made, when establishing a seismic monitoring network, is the design of the station distribution. In most cases, volcanoes are monitored with at least four to six seismic stations, which are distributed around the volcanic center. Newer deployments try to setup arrays of sensors or, even better, a network of different arrays (also named “Array of Arrays”). However, some of the design criteria deviate from the usual earthquake monitoring networks and are discussed in the following sections.

### 13.3.1 Station site selection

Considering a location as a possible site for a seismic station is always a compromise between noise considerations and accessibility. Of course, it would be best to place the seismic station far away from any human activity (see Fig. 13.19), away from big trees or sharp cliffs and ridges. However, the accessibility is very important, especially at the beginning of a surveillance campaign at a volcano. Also, the rough and harsh environment typical of many volcanoes usually requires frequent station visits for maintenance. Valleys, which generally are accessible places for seismic stations rather than ridges or cliffs, are often flooded during winter or the rainy season (not to mention the higher exposure to possible pyroclastic flows).

A second important decision must be made when choosing on “what” the station should be placed. Usually, seismologists prefer hard rock to unconsolidated sediments. At many active volcanoes, hard-rock sites are rare and, even if they exist, they are not necessarily good choices. Hard-rock sites often are small lava tongues or big blocks of lava buried in ash or soil, causing waveguide effects or even block rotation to an unknown degree. This is especially important when installing broadband seismic stations, which are very sensitive to tilt (see Chapter 5 and Fig. 13.20).

**Fig. 13.20** Simulated effect of strain-tilt coupling. The uniform input strain acts on the y-direction. As a consequence of medium inhomogeneity an assumed rigid plate (which is a placeholder for the seismometer monument) is rotated and tilted considerably. The inhomogeneity is caused by the modelled random (gaussian) medium which is represented by alternating values of Lamé's parameter  $\lambda$ . (courtesy M. v. Driel).

A network-wide homogeneous installation with good temperature isolation is preferable to apparent “hard-rock” installations (see Section 13.6 for a more detailed description). Sites near singular obstacles should be avoided such as high trees, cliffs, big towers etc., as they are likely sources of wind-generated noise. While wind noise is usually high in a frequency range  $> 5$  Hz, wind pressure is a very strong source of tilt-noise in the low frequency part ( $< 0.1$  Hz). Hence, special care must be taken when installing a broadband seismic instrument.

### 13.3.2 Station distribution

Good station coverage is crucial for nearly all monitoring efforts as well as for successful scientific research. A good choice is to install a network at two scales - one large scale network extending into non volcanic regions ( $\Delta < 20$  km) and one network with stations concentrated on the flanks and on the top of the volcano ( $\Delta \sim 0 - 2$  km). The large-scale seismic networks are very useful to distinguish between volcano-seismic signals and regional or local earthquake activity. Also the larger dimension improves the localization accuracy for deep-seated sources of magmatic activity. On the other hand, most of the seismic signals at active volcanoes are very shallow, usually small in amplitude and additionally influenced by strong scattering and high attenuation path effects. For detailed studies of the volcano-induced seismic signals, most of the stations need to be placed close to the activity center(s). One or two stations should be placed as near as possible (without danger to researchers and instruments) to the active volcanic region. Other stations should be placed such as to ensure a good overall azimuthal coverage. If possible, the station spacing should be comparable to the source depth to insure good depth control. It is good to have all parts of the focal sphere surrounding a source to be sampled by seismic stations. Best results are expected when the source is located within the station network, both lateral and vertical.

If a broadband seismometer is available, best results are achieved if it is installed as close as possible to the active area, provided that the safety of operating personnel is assured. Most of the recorded ULF and LF signals at volcanoes are detectable only in the near-field distance range (see Fig. 13.10) as well as the effect of scattering is lower as closer the station is located to the active source region (Section 13.4.5). For the best characterization of shallow low and ultra low frequency event source mechanisms, at least a few seismic stations should be placed as close to the crater or source region as possible. If an on-line radio link is desired, the station site must additionally be chosen such as to guarantee an undisturbed direct line-of-sight to repeaters or receivers (see Section 13.6 and Chapter 7, Section 7.3).

### 13.3.3 Seismic arrays in volcano monitoring

Modern approaches in volcano seismology are based on deploying seismic antennas (arrays) at active volcanic areas. Stations in an array should be spaced close enough to sample a wavefield several times in a wavelength, often requiring a spacing of about 100 m. The main advantage of such antennas and the application of array techniques is the improvement in evaluating the radiated wave-field properties, velocity structure and the source location (see Chapter 9). A comprehensive review paper dealing with standard seismic array techniques at volcanoes has been published by Chouet (1996b).

Most of the problems in operating a seismic array at an active volcano are of a technical

nature. The requirements on array site conditions are demanding, the cost of array components are rather high, and the installation and maintenance of an array during different activity stages and weather conditions require significant economic and human resources. Such requirements generally preclude the long-term use of arrays in volcano monitoring. Therefore, most of the work done so far in using array techniques at active volcanoes were short-term deployments of occasionally large arrays. Despite the mostly short duration of deployment, however, much information was gathered during these experiments. The results range from a more comprehensive description of the wave-field properties (Saccorotti et al., 1998; Chouet et al., 1997) to tracking the source volume of volcanic tremor signals (Almendros et al., 1997; Furumoto et al., 1990).

### 13.3.4 Array of seismic arrays

In attempting to achieve both monitoring and research objectives, a good compromise is to establish a network of small-aperture seismic arrays. The advantage compared to single (dense) array applications is the better spatial evaluation of the wave-field properties as well as the better azimuthal coverage when focusing on the location of the different seismic signals. In any event one has to compromise between aperture, number of instruments, spatial sampling and station accessibility. In 1997, a network of small-aperture arrays was established at the Merapi volcano, Indonesia (see Fig. 13.21). This network consists of three different array sites distributed around the volcano. The main objective of this array configuration is to attempt the automatic classification of the volcano-seismic events on the basis of the wave-field properties and an automatic hypocenter determination of the classified volcano-seismic events (Wassermann and Ohrnberger, 2001).

**Fig. 13.21** Example of a combined seismic array/network approach at Mt. Merapi volcano. The stars show the location of broadband seismometers, whereas the circles mark the position of three-component short-period seismometers, in total forming three small-aperture arrays. The diamond symbols show the location of seismic acoustic stations (short-period sensors with a microphone array).

Before installing a network of arrays, a detailed plan of features to be investigated and criteria to be met should be made, e.g., required spatial coverage and resolution, accuracy of hypocenter determination, shallow and/or deep seismicity, broadband signals etc. A good choice is a network with at least four different array sites. Each array should consist of one three-component broadband seismometer as central station surrounded by three to six short-period, vertical-component seismometers deployed in a configuration which fits best the number of seismic stations (see Chapter 9). The most suitable distance between related seismometers must be carefully evaluated during the initial stage of the setup. Decisions must be made between the peak values in the spectral domain and the desired coherence band of the signals recorded. Ideally, the stations should be roughly 100 to 200 m apart from each other (Fig. 13.21). Reducing the inter-station distances with the same number of seismometers will cause an undesired loss of resolution in slowness due to the smaller aperture and also increase the noise coherence (see Fig. 13.22).

**Fig. 13.22** Time-frequency coherence plot of a) the station combinations GRW0- GRW1 and b) GRW1-GRW2 (see Fig. 13.21). The seismometers in a) are deployed 170 m from each other, whereas in b) GRW1 and GRW2 are separated by roughly 300 m. Note: the signal coherence is computed in a sliding window with the time axis centered at the middle of the sliding window. High coherence above 2 Hz is only visible in the very beginning of a seismic event, indicating an array wide coherent phase arrival. It is also obvious that the overall coherence is somewhat lower in b) than in a) indicating the reduced signal coherence at more separated stations. On the other hand the noise coherence is also reduced in b) which improves the signal to noise ratio of the semblance estimation significantly.

## 13.4 Analysis and interpretation

In this chapter, we will briefly review the basic techniques of analyzing volcano-seismic signals. Most of the described concepts are based simply on visual pattern recognition abilities of the responsible interpreter. The last two sections will discuss more recent and objective approaches that attempt to automate these tasks.

### 13.4.1 One-component single station

Most of the observations made in the 60's and 70's were obtained by using only a few instruments located at most active volcanoes. Since then, nearly all well-monitored volcanoes are equipped with at least four to six instruments and, for a number of volcanoes, dozens of instruments. However, the basics of the classification scheme discussed in Section 13.2 is deduced by the single station approach and even today the statement “better one than nothing” holds regarding the number of deployed instruments. This is especially true when initiating short-term projects or monitoring very remote volcanoes.

#### 13.4.1.1 Spectral analysis

With the advent of inexpensive, portable and efficient computers, spectral analysis became an increasingly important tool for monitoring the activity of an active volcano. As mentioned already in Section 13.2, most of the classification is based on the time-frequency characteristics of seismic signals. Volcanic tremor episodes were distinguished by their spectral shape and appearance. There are many different techniques for computing the spectral seismic amplitude such as *Seismic Spectral Amplitude Measurement* (SSAM; Rogers and Stephens, 1991), short-term Fourier transform or power spectral density estimates, which provide the observer with signal information in the spectral domain (e.g., Qian and Chen, 1996). An important feature of volcano-seismic signals is their narrow-band spectra. In particular, volcanic tremor sometimes shows just one dominant spectral band with a bandwidth as small as 0.2 Hz. This is the reason why it is often called “harmonic tremor”. Monitoring the changes of spectral properties is a useful tool not only for signal discrimination but also for characterizing the state of volcanic activity. An example is given in Fig. 13.23. In Fig. 13.23a the total power in the frequency range between 0.6 and 3.0 Hz is plotted as a function of time. This frequency range was chosen because of its importance in discriminating between rockfall and pyroclastic flow signals (see Section 13.2.2.3). Three pronounced peaks are obvious with amplitudes well above the average value. The peaks at day 9 and day 18 are associated also with a significant increase of the power density between 2 to 10 Hz (Fig. 13.23b). On the other hand, the sharp peak in day 14 in Fig. 13.23a seems to be of a different nature and might be caused by a regional or teleseismic earthquake. The remaining times with high power density amplitudes in b) might be due to small pyroclastic flows or rockfall.

At Mt. Etna (Italy), Cosentino et al. (1989) reported a significant frequency shift in the volcanic tremor spectra prior to a flank fissure eruption. The authors detected a significant shift to lower frequency values of the dominant spectral peaks of volcanic tremor just several hours before the opening of flank fissures.

Because the efficiency of today's computers is rapidly increasing, a good choice would be to calculate complete spectrograms (or periodograms) first and decimate the amount of data only in a later step (e.g., to SSAM). This would allow the extraction of any hidden information in a later “off-line” step of the analysis without any redundant work load. Crucial in this context is a good knowledge of the possible features of different signals and their relationship to the state of volcanic activity at a specific site. It must be emphasized that stations of monitoring networks at volcanoes should be maintained for years (even decades) without any changes in the system (gain, position etc.). When upgrading an old station to new “up-to-date” technology, a sufficient overlap of both systems should be guaranteed. This precaution cannot

be overemphasized.

**Fig. 13.23** a) shows the the total power (per 60 minutes) calculated in the frequency band between 0.6 - 3.0 Hz from 01 - 19th July 1998 at Mt. Merapi, displayed on a logarithmic scale. Two of the visible peaks (i.e., day 9 and day 18) are associated with pyroclastic flows, while the sharp peak visible at day 14 is caused by a regional earthquake. b) the power spectral density vs. time in the same time range, where the box shows the frequencies used for total power plotted in a).

#### 13.4.1.2 Envelope, RSAM and cumulative amplitude measurements

An important source of information which can be deduced by small networks is the overall appearance of the signal shape in the time domain. This is important both for event classification (e.g., volcanic tremor, rockfall etc.) as well as for monitoring changes in the seismic activity of a volcano. A very efficient tool for visualizing increasing seismic activity is the *Real-Time Seismic Amplitude Measurement* (RSAM) technique proposed by Endo and Murray (1991). In its original form, RSAM was designed for analog telemetry and consisted of an A/D converter, averaging of the seismic signal in 1 min or 10 min intervals and storing of the reduced data on the computer:

$$RSAM(iT) = \frac{1}{T} \sum_{t=iT-\frac{T}{2}}^{iT+\frac{T}{2}} |s(t)|$$

Here  $T$  is the averaging interval (originally 1 or 10 min) and  $s(t)$  the sampled seismic trace. Various examples for successful applications of this technique are given by McNutt (2000b).

Some applications try to normalize the records from several seismic sensors located at different distances from the volcanic center by correcting the measured seismic amplitude for the assumed source distance (McNutt, 2000b):

$$D_R^b = \frac{Ar}{2\sqrt{2}G}, \text{ and } D_R^s = \frac{A\sqrt{\lambda r}}{2\sqrt{2}G}$$

where  $D^b$  and  $D^s$  are the reduced amplitude for body and surface waves, respectively.  $A$  is the peak to peak amplitude in centimeters,  $r$  the distance to the source,  $\lambda$  the seismic wavelength in cm and  $G$  the gain factor (magnification) of the seismic sensor. The main difference between these two equations are the different correction terms for the geometrical spreading and the effective wavelength. The reduced amplitude measurements should be considered as a pure observation parameter without any physical meaning. It should definitely not be used for the physical interpretation of an ongoing eruption. The reduction of the seismic amplitude assumes specific modes of wave propagation, i.e., body wave and surface waves, respectively. As there is no reliable estimate of the wave-field properties, it is possible with just one or a few seismometers that the assumption of the degree of geometrical spreading is highly speculative. Also the effect of site amplification and the strong scattering observed frequently at volcanoes (Wegler and Lühr, 2001), which depend in general on the source location, structure and topography of the volcano, may alter the amplitude-distance relationship significantly. They are neglected in this approach.

Another way of displaying changes in the radiated seismic wave-field is based on the computation of the de-trended cumulative radiated power of the seismograms at a single station (see Fig. 13.20):

$$P_{cum}(f_{1-2}, t) = \sum_t \left( \sum_{f=f_1}^{f_2} P_t(f) - trend \right)$$

with  $P_t(t)$  being the power spectral density during the time interval  $t$  and  $f_1, f_2$  the lower and upper frequency for computing the cumulative power. *trend* is the slope of the cumulative power, calculated during a quite time period, i.e., baseline activity of the volcano (Fig. 13.24).

**Fig. 13.24** De-trended cumulative power of the vertical components of all broadband seismometers at Mt. Merapi during 1998 activity. The red lines mark the occurrence of two pyroclastic flows. A steep increase of the total cumulative power 10 days before the onset of the first pyroclastic flow is visible, following a period with very low seismicity. Also the second eruption is preceded by an increase of cumulative power at two stations, while one station (blue) was out of operation. The background trend was estimated during a low activity phase in 1997.

To avoid a fast saturation of the cumulative power values, a good way is to estimate the slope of the cumulative power when the activity of the volcano is on its baseline. This estimated trend can be removed for each time step resulting in a de-trended cumulative power plot, which shows strong deviation from the “normal” background seismicity. Furthermore, cumulative power can be used to analyze certain frequency bands (see Fig. 13.23a), unlike the power change in time, which resembles the method of RSAM. In Fig. 13.24, the de-trended cumulative power of three broadband stations at Mt. Merapi is shown. Note the steep increase of seismic power roughly ten days prior to the first eruption. A further increase in cumulative power is obvious for two stations preceding the second large pyroclastic flow. The third station was out of operation caused by ash fall on the solar panels.

A common way to display information on the current status of a volcano is to count the different seismic event types in a hourly or daily manner (Fig. 13.25). While the physical interpretation of the type of event is sometimes impossible when using only one station, such event/time plot is an excellent tool for displaying all information (objective and subjective)

within one single plot. There are many papers, which rely strongly on this kind of activity measurements. Most of the observations are summarized by McNutt (1996, 2000b). Also in this case, we must emphasize that, without a complementary detailed seismological study, this is just a visualization of observed patterns with, strictly speaking, unknown physical meaning.

**Fig. 13.25** Event-type per day plot during the high activity of Mt. Merapi during July 1998. Note the increase of the three event classes before the onset of the first pyroclastic flow. Also note the similarity of the VT-B type event curve to the occurrence of pyroclastic flows (courtesy of VSI- BPPTK, Yogyakarta).

Whatsoever, if knowledge about the hypocenters (see Section 13.4.3.1) and even source mechanism is available these event-time plots are very valuable in order to evaluate the activity state of a volcano. At Soufriere Hills volcano (Montserrat island) it was possible to distinguish different activity phases with the help of these seismicity plots (Miller et al., 1998). Just before the surface activity starts to develop a swarm of VT-A earthquakes appeared. During cycles of inflation in the upper part of the growing dome a large number of Hybrid and LP events were detected. Finally, a large number of surface events, mainly rockfall signals, were recorded as the dome became more and more unstable. While this pattern of seismic signals is very important during a high activity phase of a volcano, it must be emphasized that every volcano and every eruption has its own unique pattern.

#### 13.4.1.3 Failure Forecast Method (FFM)

While the FFM originates from material sciences and relates the rate of precursory signs of failure to the likeliness of failure, Voight (1989), Cornelius and Voight (1995) and Kilburn (2003) introduced an early warning method, which is based on the rate of precursory signs (e.g., number of a certain type of seismic signal, RSAM, cumulative tilt etc.) and correlates their accelerations to the onset time of an eruption. The governing equation is given by:

$$\partial^2 \Omega / \partial t^2 = A(\partial \Omega / \partial t)^\alpha$$

where  $\partial^2\Omega/\partial t^2$  and  $\partial\Omega/\partial t$  are the acceleration and rate of the monitored parameter.  $A$  and  $\alpha$  are empirically determined parameters. Cornelius and Voight (1995) pointed out that  $\alpha$  evolve from 1 to 2 before an eruption. Kilburn (2003) pointed out that the peak of event rates are better suited to forecast the timing of a failure (i.e. eruption) and that  $\alpha = 2$  should be used. With this assumption the equation can be simplified to:

$$1/(\partial\Omega/\partial t) = A(t_f - t)$$

where  $t_f$  is the time of failure. Fig. 13.26 gives an example of a successful application of FFM.

**Fig.13.26** Change in recorded seismicity before the 1995 eruption of Soufriere Hills on Montserrat. Arrow E marks onset of magmatic activity. On an inverse-rate diagram, the filled triangles, which correspond to inverse-rate minima, lie along a linear trend (large dashed line). Such a trend possibly could be recognized by Day 8, which results in a maximum 6-day warning of eruption. Note that peak values are more readily identified from the inverse-rate minima than the actual event-rate maxima, and that steeper linear trends occur among individual sequences (small dashed lines) (from: Kilburn, 2003).

### 13.4.2 Three-component single station

Most modern seismometers are three-component sensors, which record the vector of ground motion produced by seismic waves. Observation of the particle motion will not help to precisely determine source locations and their variations without a detailed knowledge of the wave-field properties (e.g., Rayleigh waves, Love-waves, P- or SH and SV-waves). In some cases it might be possible to “steer” or point towards the active source region by estimating the particle motion of the very first wavelets of LF or ULF events. As this is possible mainly in the near field there might be an unknown degree of distortion. Changing patterns of particle motion may help estimate the activity changes of a volcanic system in a qualitative way, however.

### 13.4.2.1 Polarization

Seidl and Hellweg (1991) showed results from analyzing the 3D-trajectories of a single seismic broadband station at Mt. Etna volcano (Italy) using very narrow bandpass filters. They argued that the occasional strong variations in the azimuth and incidence angles of the trajectories may reflect sudden changes of the active source location. Recent experiments using array techniques showed, however, that the wave field radiated from a volcanic source is a combination of complex source mechanisms and strong path influences (e.g., Chouet et al., 1997). Hence, the wave-field consists of a mixture of many wave types and care must be taken when only polarization information is available. On the other hand, carefully extracted information and the associated changes of polarization pattern during different cycles of volcanic activity may help to identify changes in the state of the volcanic system (see Fig. 13.27 below).

The use of a broadband seismic station located close to an active vent, i.e., in the near-field, improves the quality of source estimations based on simple polarization analysis. This is because of the small influence of the propagation path in the near-field. Unfortunately, complicated source mechanisms, i.e., when the usual assumption of a point source is no longer valid, will complicate the interpretation of the observed polarization pattern to an unknown degree (Neuberg and Pointer, 2000). Also, the nearly unknown influence of the topography of the volcano on signals with a wavelength comparable to the topographic obstacle will make interpretation difficult. Near-field measurements at Stromboli volcano (Italy) showed, that in some cases, a fairly good estimation of the source region could be made using just a single three-component broadband station (Kirchdörfer, 1999; Hidayat et al., 2000) under the assumption of a simple source mechanism.

### 13.4.2.2 Polarization filters

When evaluating the polarization properties of volcano-seismic signals as part of a monitoring system, an automatic estimation of parameters is needed. Best results will be obtained when focusing on the basic parameters, i.e., the azimuth, incidence angle and a measure of the rectilinearity of the signals. Various approaches will extract this information from a continuous data stream. Most of them are based on a least-square fit of the 3D-trajectory of the seismic vector to a 3D-ellipsoid. Typical algorithms consist of solving the eigenequation and simultaneously searching for the orientation of the eigenvector corresponding to the largest eigenvalue (e.g., Flinn, 1965, Montalbetti and Kanasevich, 1970):

$$\begin{bmatrix} x_i \\ y_i \\ z_i \end{bmatrix} \left| C - \lambda_i I \right| = 0$$

where  $x_i$ ,  $y_i$ ,  $z_i$  represent the components of the  $i$ -th eigenvector,  $I$  is the identity matrix and  $\lambda_i$  is the eigenvalue according to the  $i$ -th eigenvector.  $C$  represents the covariance matrix of the 3D signal recorded:

$$C_{ij} = \sum (u_i - \bar{u}_i)(u_j - \bar{u}_j)$$

where  $u_i, u_j$  are the  $i$ -th and  $j$ -th component of the seismic sensor and  $\bar{u}_i, \bar{u}_j$  represents the mean values of the data traces within the analyzed time window. A possible way to display the polarization properties vs. time is to plot the orientation of the eigenvector associated with the largest eigenvalue (corresponding to the major axis of the ellipsoid) in the coordinate system of the sensor, i.e., its azimuth  $\Phi_{az}$  and incidence angle  $\Theta_{inc}$ :

$$\Phi_{az}(t) = \text{atan}\left(\frac{y_1(t)}{x_1(t)}\right), \text{ and } \Theta_{inc}(t) = \text{atan}\left(\frac{z_1(t)}{\sqrt{x_1^2(t) + y_1^2(t)}}\right)$$

with  $x_1, y_1, z_1$  representing the eigenvector components of the largest eigenvalue  $\lambda_1(>\lambda_2>\lambda_3)$ . Note: without any further assumption about the analyzed wave-type, i.e., P-, SH- or SV-wave etc., the computed azimuth has an ambiguity of 180 degrees, whereas the incidence angle varies between 0 - 90 degrees. Typically, a measure of the rectilinearity of the signal's polarization (i.e., the relative elongation of the ellipsoid in one direction) is computed (e.g., Vidale, 1986):

$$L(t) = 1 - \left(\frac{\lambda_2(t) + \lambda_3(t)}{\lambda_1(t)}\right)$$

$L(t)$  is only larger than 0 if  $\lambda_1$  is bigger than the combination of the other two. Fig. 13.27 gives an example of the variation of the parameters  $\Phi_{az}$  and  $\Theta_{inc}$  over a long time period at Stromboli volcano.

**Fig. 13.27** Long-term variations of incidence angle (a) and azimuth (b) in the 115 time windows selected from July 1996 to April 1999 at Stromboli volcano. In both panels, solid and dotted line depict mean value and standard deviation, respectively, computed over 5 to 7 consecutive days in the 17 time windows selected from July 1996 to April 1999. The polarization parameters were estimated using the technique of Montalbetti and Kanasevich (1970). The variation of this waveform information seems to match changes in the activity states of the volcano (courtesy of S. Falsaperla, Istituto Nazionale di Geofisica e Vulcanologia).

Because we have no knowledge of the wave type represented by the computed polarization parameters, they must be seen as varying activity parameters rather than interpreting them as part of a technique for hypocenter determination.

### **13.4.3 Network**

#### **13.4.3.1 Hypocenter determination by travel-time differences**

Modern seismic monitoring networks at active volcanoes usually consist of at least four to six seismic sensors distributed in various azimuths and distances from the volcanic center. While continuous signals such as volcanic tremor or transients like LF-events often lack any clear phase arrival, some signals (VT, explosion quake) with clear onsets can be located using standard seismological techniques.

Usually, events with clear P- and/or S-wave onsets are selected visually and the first breaks are picked interactively. The inversion for the source location is frequently done using algorithms such as HYPO71 (Lee and Lahr, 1975) or HYPOELLIPSE (Lahr, 1989) or HYP2000 (Klein, 2002). Note, however, that most of the standard hypocenter determination programs are based on the assumption of a horizontally layered half-space and/or models with linear gradients with no topography. Also new approaches exist, which are not restricted to 1D or 2D velocity models and which try to locate the sources in a non-linear, probability based manner (e.g., Lomax et al., 2000). However, in most cases no good velocity models for the monitored volcanoes exist and the computed source coordinates, especially when focusing on shallow events, must be seen just as an approximation to the true hypocenter. Relative earthquake locations of multiplets with similar waveforms can greatly improve the resolution of volcanic structures (Rubin et al, 1998; Waldhauser and Ellsworth, 2000; Ratdomopurbo and Poupinet, 1995). De Barros et al (2009) showed that when the network is dense enough such that events correlate at different station very good and reliable locations are possible using a grid search method.

There are many papers on the topic of imaging the hypocenter distribution during or before a volcanic eruption (e.g., Newhall and Punongbayan, 1996; Power et al., 1994; Chouet et al., 1994). Very useful information about the geometry of the plumbing system as well as the physical properties of the host rocks can be deduced by analyzing the time-space pattern of frequently occurring swarms of deeper earthquakes (Power et al., 1994).

Also the migration of hypocenters during a high activity phase of a volcano is important in forecasting the subsequent volcanic eruption. In Fig. 13.28 an example of the 1991 Mt. Pinatubo eruption is shown. The migration of the seismic events from a cluster at 5 km depth north-west of the volcano in A) to a very shallow location directly underneath the erupting vent in B) is very obvious and possibly marks the ascending magma.

**Fig. 13.28** A) Mt. Pinatubo seismicity during May 6 to May 31. The seismic events are clearly clustering northwest of the volcanic center. B) shows the seismicity between June 1 to June 12 indicating a shift of the hypocenters to shallow depths and closer to the summit of Mt. Pinatubo (courtesy of Pinatubo Observatory Team (1991), EOS Trans. Am. Geophys Union, 72, 545, 552-553, 555)

#### 13.4.3.2 Cross correlation of diffusive wavefields

Weaver and Lobkis (2001a), Campillo and Paul, (2003) and Wapenaar et al. (2006) showed that correlating the coda of earthquakes which are azimuthally well distributed around a seismic station pair will result in an estimate of the Greens function of the subsurface structure between these two stations. Shapiro and Campillo (2004) also showed that the Greens function, or at least parts of it can also be retrieved when using the diffusive wavefield of noise. Sens-Schönfelder and Wegler (2006) used this property to monitor the seasonal changes at shallow depth on a volcanoes flank which is thought to represent different ground water saturation. Brenguier et al. (2008) showed, that monitoring the changes of the Green's function can be interpreted as a change in the velocity field at a volcano. This change is caused by the deformation of the volcanoes edifice caused by inflating or deflating magma. Fig 13.29 gives an example.

**Fig. 13.29** (A) Relative velocity perturbations associated with the second eruption precursor (day 85, Sept. 1999) at Piton de la Fournaise volcano (Reunion island). The gray dashed line represents the limits of ray coverage. (B) Fast shear velocity anomaly imaged by passive surface wave tomography (and interpreted as an effect of solidified dykes associated with the zone of magma injection). (C) Relative time perturbations before the eruption of July 2006. (D) Associated regionalized relative velocity perturbations one day before the beginning of the eruption (from: Brenguier et al., 2008)

While in praxis the technique is rather complex and sophisticated, parts of it are already included in daily monitoring routines (e.g., EARTHWORM, see Section 13.4.6).

### 13.4.3.3 Amplitude - distance based hypocenter determination algorithms

Even in the case of no clear P- or S-wave arrival, it is sometimes possible to estimate an approximate source area. Assuming a certain wave type (body or surface wave), neglecting an uneven radiation pattern of the source, and assuming a simplified propagation path, it is possible to compute amplitude-distance curves and model the source region. This can be seen as an iterative approach of fitting or contouring the amplitudes or radiated energy measured in the whole network. Successful applications of this technique were reported for locating volcanic tremor at Bromo volcano, Indonesia (Gottschämmer and Surono, 2000) and Mt.

Etna, Italy (Cosentino et al., 1984). However, care must be taken in the a priori assumption of the wave-type, i.e., body or surface waves. When locating the paths of pyroclastic density at Soufriere Hills volcano (Mountserrat), Jolly et al. (2002) were using a surface wave relationship. Battaglia et al. (2005) showed that volcanic tremor can be successfully located (see Fig. 13.30) by applying a rather simple amplitude-distance relationship. However, Battaglia et al. (2005) clearly pointed out that before applying this technique to the data a so called coda normalization has to be done in order to remove station-site dependent amplifications (Battaglia et al., 2005).

**Fig. 13.30** Example of an individual location in the 5–10 Hz frequency band for a tremor sample collected during the 1998 eruption of Piton de la Fournaise volcano (Reunion island). Map view and NS and EW cross-sections are shown. The result of the location is plotted as a white star, which is superposed on the normalized error contours. (from: Battaglia et al., 2005)

Wegler and Lühr (2001) and Friedrich and Wegler (2005) showed that the largest amplitudes visible in the seismograms recorded at the Mt. Merapi volcano are fitted best by assuming a strong scattering regime (see Fig. 13.31), which also alters the amplitude-distance relationship.

**Fig. 13.31** **a)** Envelope of MP event measured at different stations around Mt. Merapi and the result of fitting the scattering relationship of Wegler and Lühr (2001) to the data. **b)** shows the stack of locations of several hundreds of MP events using this amplitude distance relationship.

Also the influence of near-field effects may influence the amplitude-distance curve significantly (see Fig. 13.32).

**Fig. 13.32 Top:** Amplitude-distance relationship at Stromboli volcano. The amplitudes were measured in the frequency range 0.04 - 0.08 Hz. The best fit of the amplitudes at different distances from the active vent was obtained when an additional near-field term was added ( $A \sim 1/\Delta^2$ ). **Bottom:** Same as top diagram but in the frequency range 0.3 - 0.7 Hz. In this case the best fitting curve follows the usual factor of geometrical spreading  $1/\Delta$  for body waves. It is also obvious that in b) site effects are more pronounced than in a).

Amongst others the following relationships have been proposed:

- body waves (Battaglia et al., 2005):  $A^2 \sim A_0^2/r^2$ ;
- surface waves:  $A^2 \sim A_0^2/r$  (Jolly et al., 2002);
- near field:  $A^2 \sim (A_0/r + B_0/r^2)^2$  (Wassermann, 1997);
- scattering:  $A^2 \sim A_0^2 (1/(2\pi dt))^{3/2} \exp\{-bt - r^2/4dt\}$  (Wegler and Lühr, 2001)

#### 13.4.4 Seismic arrays

The analysis of seismic signals using array techniques is seen as the most prominent and emerging modern tool for locating volcano-seismic signals and evaluating the seismic wave-

field properties (e.g., Chouet, 1996b). While most of the array techniques are discussed in Chapter 9, we will focus on some results obtained when applying them in volcano monitoring and signal analysis.

The main deviation from typical array techniques in earthquake seismology is that the height differences between the array stations can not be neglected when the array is deployed on the flanks of a volcano. The effect of a 3D-distribution of stations can be minimized by fitting a plane to the station locations which dips according to the topography. One then transforms all auxiliary information (i.e., station coordinates) and refers all estimated parameters (incidence, azimuth and horizontal slowness) to this “best fitting plane”.

#### **13.4.4.1 f-k beamforming**

One of the most useful properties of a seismic array is its capability for suppressing undesired signals by filtering the incoming wave-field in the spatial as well as in the frequency domain. Thus, we can estimate the coherence, the signal power, the azimuth and the apparent velocity of an incoming wave. Because most seismic signals map into different regions of the frequency-wave number plane (see, e.g., Fig. 9.28, 9.38 and 9.40), f-k beamforming is an excellent tool to distinguish between the different wave-types. Beamforming can be thought of as delaying each seismic trace in time such that waves will add constructively when summed. The delay times necessary to obtain maximum “beam-power” is used to determine the direction of wave propagation through the array. Beams “aimed” in a direction, which is different than the true source direction will add destructively and produce a low signal. If the seismic array is located several wavelength from the assumed source area and the spatial extend of the array is small compared to the distance towards the source, we can also assume plane-wave propagation. Under these assumptions it is possible to estimate the backazimuth towards the source and, if the velocity model directly below the array is known, we can also estimate the incidence of the incoming plane wave. We can then invert for the source area of the signal (see Chapter 9, Sections 9.4.2 - 9.4.4).

Fig. 13.33a-e) gives an example of a broadband f-k analysis with data recorded at Mt. Merapi. Obviously only the very first part of the signal shows a phase with high coherence b), which additionally shows a small slowness c) (high apparent velocity). In contrast, later arrivals have randomly fluctuating backazimuth and slowness values. A possible interpretation of this pattern is that the recorded event consists of an array-wide coherent body phase (indicated by the high coherence and red color coding), which could be used for locating the event combining the backazimuth information and, if the velocity model just beneath the array is known, the incidence angle is estimated from the slowness. This coherent phase is followed by randomly incident waves.

Thus, the potential of a seismic array to discriminate between various types of incoming seismic waves and to quantify their properties makes the f-k beamforming perhaps the most powerful tool for investigation of continuous signals (i.e., volcanic tremor). Furumoto et al. (1990) and Almendros et al. (1997) showed the results of tracking a volcanic tremor source in space and time using seismic array beamforming. Other applications of large seismic arrays have been reported by Saccorotti et al. (1998), Chouet et al. (1997) and La Rocca et al. (2000), to name a few.

However, the application of beamforming techniques in volcano monitoring requires high computer power, rarely available during a volcanic crisis. In order to reduce it, one can use the spatial filter properties of seismic arrays and apply the f-k beamforming to steer in one or several directions of special interest (similar to beamsteering used to detect underground nuclear explosions; see Chapter 9, Section 9.6 and Section 9.7.7). Another way to reduce computational processing includes optimization of estimating the maximum of the beam in the f-k plane (i.e., highest coherence value) by using simulated annealing and/or simplex techniques (Ohrnberger, 2001).

#### **13.4.4.2 Array polarization**

As three-component seismometers are becoming the standard instrument nowadays and seismic arrays consist frequently of large numbers of three axial sensors, it is also possible to evaluate the polarization properties of the whole array. While there is no straight-forward method to include the polarization properties directly into the f-k-algorithm, it is possible to estimate array-averaged parameters of the 3D-trajectories. Jurkevics (1988) showed that array-wide averaging of the covariance matrices (see Section 13.4.2.2) results in a more stable estimate of the seismic wave vector (Fig. 13.27). Jurkevics (1988) also demonstrated the insensitivity of this estimate to alignment problems within the array. With this algorithm it is also possible to average the polarization properties over certain frequency bands which is a further link to the averaging properties of the broadband f-k-analysis (see Chapter 9, Section 9.7).

A further method to incorporate three-component seismic recordings of an array is to compute the “waveform” semblance (e.g., Ohminato et al., 1998; Kawakatsu et al., 2000). This approach consists of a grid search over possible source locations and the simultaneous rotation of the 3D ground motion vector towards these hypothetical sources. The semblance value of the L direction (L-Q-T system defining the direction from the source to the station L, the plane Q perpendicular to L including the source and receiver and the plane T perpendicular to Q) is computed. Assuming a source which generates solely a compressional wave in L direction the energy-density on the orthogonal components should be zero. Finally the “waveform” semblance should be 1 if the signal is coherent on all array stations and if no energy is left on the two directions perpendicular to L. The “waveform” semblance should be zero if there exists only incoherent wave-groups and/or there is still signal on the components different to L. It must be emphasized that this approach is restricted to cases where path effects and the influence of the free surface has no or vanishing influence on the orientation of the particle motion, i.e., low-frequency near-field observations.

#### **13.4.4.3 Hypocenter determination using seismic arrays**

As described in the Section 13.4.4.1 it is possible to track seismic sources in space and time using seismic arrays. Unfortunately, the exact seismic velocity distribution of a volcano is unknown. This results in large uncertainties in estimating the location of volcanic-seismic sources. One possible solution is to use not only one array but a network of arrays distributed around the volcano to compute the backazimuth of the coherent arrivals for each array separately and to invert them for the epicenter of the signal. Applications of this technique can be found in La Rocca et al. (2000).

Another difficulty arises when the seismic array is located close to the source and/or the height differences between the array stations are not negligibly. In this case the usually assumed plane wave propagation is no longer a good approximation and therefore the results are biased to an unknown extent, because neither the influence of the topography nor the deviation of the wave front from a plane wave is exactly known. In this case, a better way to localize the seismic source is to apply a more complicated approach, which first uses f-k beamforming to detect coherent phases within the continuous seismic data records and then apply two station generalized cross-correlation techniques in order to estimate the time difference of arrivals between the two stations. Wassermann and Ohrnberger (2001) successfully applied this technique to localize VT and strong MP events recorded at Mt. Merapi without the need for interactively determined onsets.

While this algorithm is only applicable to coherent and transient signals, algorithms exist which are based on the migration of coherent phases back to the source region (Almendros et al., 1999; Ohminato et al., 1998; Wassermann, 1997). Unfortunately, the computational load of these algorithms is high and their application is restricted to the “off-line” analysis of selected signals of special interest.

### **13.4.5 Automatic classification/detection**

When establishing a seismic network at an active volcano it is also possible to revise the classification scheme used (it would be possible even with a single station, but not very reliable). Besides the usually semi-automatic trigger and (visually) applied time-frequency analysis (see Section 13.4.1.1), we can also use wave-field properties obtained from the array analysis to enhance our discrimination quality significantly.

The advances in performing an automatic classification during the last 10 years are tremendous and can be separated in two major groups. Group one uses pre-triggered data, which are then classified by a combination of Self-Organizing-Maps (SOM) and Neural Networks (NN). See Scarpetta et al. (2005) and Esposito et al. (2008) for further information. The drawback of these methods is that the detection problem, i.e. to separate signal from noise, has to be solved in advance at least for the currently available algorithms.

Ohrnberger (2001) was the first who applied Hidden Markov Model (HMM) based speech recognition techniques on parameters deduced from a continuous array analysis using data recorded at the Mt. Merapi volcano. Fig. 13.25 from Ohrnberger (2001) gives an example of the output of the continuous parameterization using seismic array techniques. The HMM approach solves the detection/classification problem in one single step by applying the double stochastic model which connects a Markov chain with the probability of observation parameters. Meanwhile a couple of applications exist (Beyreuther et al., 2008; Ibanez et al. 2009) where both groups are using the HTK-Toolkit for efficient computation of the classification probabilities. Fig. 13.34 gives an example of manual vs. automatic, HMM based detection and classification with data recorded in 1998 at Mt. Merapi volcano. Beyreuther and Wassermann (2011), also point out how the application of a slightly different stochastic model can improve the result significantly. In order to speed up the training and to ensure the flexibility of the classification, a guided training algorithm was developed as part of the EXUPERY project (see Section 13.6.5) by C. Hammer. This software is based on the python package ObsPy ([www.obspy.org](http://www.obspy.org), Beyreuther et al., 2010), can be incorporated into the EARTHWORM system (see Chapter 13.4.7) and is available via the project website [www.exupery-vfrs.de](http://www.exupery-vfrs.de).

**Fig. 13.34** Continuous classification using an automatic HMM based algorithm vs. human interpreter for seismic events from Mt. Merapi in 1998. The light red bars correspond to the classification results of the HMM classification, the blue bars correspond to the classifications of the local expert. The green triangle marks the onset of an eruption. The bars are transparent, thus a blue bar overlaid with a light red bar results in a purple bar (courtesy: M. Beyreuther).

### 13.4.6 Moment tensor inversion

In the recent years various approaches were made to investigate the dynamics of the different sources of the VLF and ULF signals using moment tensor analysis. While the estimation of the centroid moment tensor became a standard technique in earthquake seismology (e.g., NEIC and Harvard rapid moment tensor solutions), the application of this technique in volcano seismology is still restricted to specific applications or frequency ranges. The difficulties are manifold. First of all the influence of topography is neglected in the standard approaches, which results in large misfits of the computed synthetic Green's functions. Moreover, Ohminato et al. (1998) show that even when assuming a horizontal layered medium, the knowledge of the source location and velocity model with a high confidence is needed in order to apply this technique.

**Fig. 13.35** Data (thick) and synthetic (thin) seismograms calculated from a inversion of the seismic moment tensor for a single pulse of *long period tremor* at Aso volcano. The corresponding source mechanism consists of a large isotropic component (97%) in addition to a small deviatoric part (Legrand et al., 2000).

Compensated linear vector dipole solutions (CLVD) are often biased by the uncertainty of the assumed simplified velocity structure. However, there are some applications of moment tensor estimations with VLF and ULF signals which gave reliable results, indicating source mechanisms which deviate significantly from a pure double-couple solution commonly known of tectonic earthquake mechanisms (e.g., Fig. 13.35 from Legrand et al., 2000; Ohminato et al., 1998; Aoyama and Takeo, 2001; Saraò et al. (2001).

#### 13.4.6.1 Computation of Green's functions in 3D

The “day-to-day” increasing computer power combined with recent advances in computing synthetic seismograms (particle based methods: O’Brien and Bean, 2004; ADER-DG: Dumbser and Käser, 2006; Käser and Dumbser, 2006) makes it now possible to estimate Green’s function in 3D up to high frequencies for medium sized problems. Due to the still enormous computer cost, the application of these techniques is restricted to institutions with

sophisticated (parallel) computational infrastructure. One of the first attempts to include the topography of a volcano into the simulation process or Green's function calculation was published by Ripperger et al. (2003). In their simple stair case model the authors already showed the importance of topography as a prominent scatterer in the higher frequency parts of the spectra. For the definition of the Greens function please see Chapter 3 of this manual and the paper by Graves and Wald (2001).

In a series of papers Bean et al. (2008), O'Brien and Bean (2004, 2009), Lokmer et al. (2007) and De Barros et al. (2011) impressively demonstrate the severe effects of topography, unknown velocity structure and source location on the inverted source mechanism. When not properly tested this will lead to completely wrong results where much of the error is projected in non-“double couple” parts of the inverted moment tensor. De Barros et al. (2011) also showed that the misfit or in other words “misleading forces” (see Section 13.4.5.2) can be reduced when observing volcanic signals in their near field and in a reduced frequency range. While scattering plays no important role for frequencies below, e.g., 0.2 Hz, the topography significantly change the Green's function and therefore, when not corrected for, causes severe errors in the resulting moment tensor. Additional sources of errors are uncorrected tilt signals especially when horizontal components of recorded seismograms are used and the unknown amount of strain-tilt coupling which is caused by local heterogeneities directly at the installation site of the deployed sensor (see Section 13.3.1)

#### **13.4.6.2 Source modeling of complex processes**

In theory nearly every seismic source known in earthquake seismology or related fields can successfully be modeled by an arbitrary moment tensor or by a combination of several moment tensors. However, when interpreting seismic signals of volcanic origin sometimes additional forces are needed in order to explain the recorded seismograms. Cesca and Dahm (2008) showed, that the 2005 paroxysmal eruption of Stromboli volcano can be modeled best by a combination of a moment tensor representing a CLVD (see chapter 3 for nomenclature) and a vertical orientated single force. The latter is often thought to represent the acceleration of the slug towards the surface. James et al. (2009) however show, that the single force is modeled best by a down flowing and thus accelerating viscous fluid.

A complete different explanation is given by De Barros et al. (2011). In numerical studies they can show, that the modeled single force often represent a sort of “trash can”, which includes all unknowns of the source process itself, the propagation media or instrumental problems.

Chouet et al. (2010), Chouet et al. (2008), Aster et al (2008) and De Barros et al. (2011) show that the combination of different geometrical bodies (cracks, cylinders, spheres), may lead to a successful minimized least squares representation of the seismic source (see Fig. 13.36). However, we should keep in mind that this representation only models the seismic part and may not explain the physics leading to a volcanic eruption correctly. Only few percent of the momentum during the ascent of magma or a volcanic eruption is transferred into elastic momentum, i.e., seismic waves. In order to shed more light into the process of volcanic eruption different measurements representing different physical aspects must be taken into account (see Section 13.5).

**Fig. 13.36** Dominant source component (red) and sub-dominant source component (grey) of a degassing burst at Kilauea volcano (Hawaii, USA). Different geometries are compared and the residual errors are shown in parentheses at the upper right (from Chouet et al., 2010)

### 13.4.6.3 Limitations of Moment Tensor Inversion

Many limitations were already mentioned while discussing the computation of Green's function and source modeling. Unknown velocity model, source time function, tilt motions on the horizontal components and/or tilt-strain coupling and our limited knowledge about the physics of ascending magmatic material will naturally lead to a rather blurred view of the source processes in a volcanic conduit.

Still unknown are also the influences of scattering and the violation of the commonly used point source assumption. While the latter may lead to a wrong representation of the forces involved, the scattering of the wavefield will gain more importance when the focus is put on the observation, processing and thus detailed modeling of higher frequencies. Possible ways out of this dilemma will lead to even more complex and costly (i.e., computational time) simulations and modeling of the recorded wavefield. The strong scattering usually present at active volcanoes, however, may form a natural frequency limit of interpreting the seismo-volcanic sources.

### 13.4.7 Automatic analysis and databases

During a seismic crisis or in the framework of a long-term seismic surveillance, it is not possible to apply all the analysis tools described above in a visually controlled, interactive manner. During the October 1996 volcanic crisis at Mt. Merapi nearly 5000 events/day occurred. This large number of events obviously precludes any on-line, interactive analysis of the seismic data.

There are various approaches to automate at least some parts of the routine analysis in a volcanic observatory (e.g., Patanè and Ferrari, 1999). The most prominent software package is called EARTHWORM (Johnson et al., 1995), developed mainly under the auspices of the U.S.G.S. Many of the techniques described above are implemented in this “real-time” environment, e.g., continuous spectral analysis, RSAM, SSAM, automatic event associations, hypocenter location and magnitude. Mainly designed for monitoring local earthquakes, its widespread use at volcano observatories has led to the development of new, volcano related modules and promises new tools in the future. The EARTHWORM system appears to be very flexible and capable of being adapted to special requirements at different volcanoes. However, the great flexibility of this software package entails rather complex and unwieldy setup procedures when establishing the system the first time.

Also quite widely used is the system SEISAN (Ottemöller et al., 2011, for the latest release: <http://seis.geus.net/software/seisan/>). In strict sense not an on-line system, SEISAN combines flexibility, open source character and a stable but simple interactive environment, which altogether form an attractive tool for the global volcanic community.

While writing the revised chapter of this manual, several new developments were made in the framework of automatic, near-realtime analysis of seismic signals at active volcanoes. Next to now established LINUX/UNIX/MAC and WINDOWS versions of EARTHWORM (Johnson et al. 1995, [www.isti.com](http://www.isti.com)) new systems are now available which may in future replace parts or the whole systems now currently running at volcanic observatories. E.g., seiscamp3, originally developed in the aftermath of the fatal 2004 Sumatra tsunami, is finding increasing applications within the global seismological and volcanological community ([www.seiscamp3.org](http://www.seiscamp3.org)). While the majority of the routines, especially the data retrieval (seedlink protocol: <http://geofon.gfz-potsdam.de/geofon//seiscamp3/>) is under GNU license, parts of the GUI, i.e., interactive parts are under binary license only. Currently seiscamp3 focuses on real-time analysis of seismic signals and thus needs a volcanological extension.

A volcanological extension of EARTHWORM and seiscamp3 offers the newly developed geophysical database SeisHub ([www.seishub.org](http://www.seishub.org)), which was partly developed during the Exupery-project (see Section 13.6.5). Using a combination of a SQL-database (incl. the command set) together with XML structured documents it forms a very flexible way to store and retrieve information with geophysical content. It is especially able to store all parameters and data described in Section 13.5, regardless of whether the data consists of time-amplitude values or sequences of 2D images. The SeisHub database extensively uses a package named ObsPy ([www.obspy.org](http://www.obspy.org)), a python based library for unified input/output and analysis techniques. With its possibilities to connect or include parameters from seiscamp3 and EARTHWORM as well the possibility to connect to data centers via arclink/fissures/seishub, ObsPy closes the gap between real-time algorithms and more specialized application needed in volcanology.

Also the World Organization of Volcano Observatories (WOVO; [www.wovo.org](http://www.wovo.org)) is currently developing a SQL/XML database hybrid (WOVOdat; [www.wovodat.org](http://www.wovodat.org)) able to store different parameters estimated or recorded at volcanic observatories around the world. The main focus of this data collection is to provide local observers with observations made at different volcanoes in order to enable a reliable estimation of unrest at “her/his local” volcano by comparing the surveillance parameters with that made at similar volcanoes.

## 13.5 Other monitoring techniques

As described at the beginning of this chapter, seismology is generally seen as the most reliable and diagnostic tool for monitoring a restless or erupting volcano. However, data from seismological surveillance alone are inadequate to understand and forecast eruptions. Modern monitoring systems will therefore combine seismology with other geophysical, geochemical, geodetic and geological techniques. In this section we focus on just a few of the various ground-based monitoring techniques which are closely related to seismology. We will not discuss the wide and fast-developing field of remote sensing in a volcanological context.

### 13.5.1 Infra sound

A method closely related to seismology consists in recording the infra sound produced by shallow volcanic processes. While the idea of recording infra sound is relatively old (e.g., Ripepe et al., 1996; Reed, 1987), the fields of application, instrumentation and theory is fast expanding. Most of the infra sound measurements are performed at volcanoes which show strombolian or hawaiianian activity. In this case the burst of large gas pockets (slug or annular flow) will produce large sonic signals which are recorded best in the infra sound range (Fig. 13.37).

Johnson et al. (2008) and Gerst (2010) show how the recordings of infra sound can help to estimate the overpressures of the bursting gas slug. Gerst (2010) however, pointed out that infra sound recordings alone will give wrong estimates of overpressures and bubble burst dynamics. Using additional measures taken by a Doppler radar instrument Gerst (2010) was able to develop a physical model how the bubble is bursting at the magma air interface. While the dynamics of the bursting bubble in this model is controlled by the kinetic and potential energy of the expanding bubble shell, the overall budget is dominated by the thermal energy of hot lava ejecta (Gerst, 2010). The overpressures at Mt. Erebus volcano (Antarctica) remain small (3-7 bar) in relation to the violence of the eruptions. This is of great importance also for seismology at this type of volcano as it is then possible to better model the seismic coupling of the volcanic (fluid-gas) source to the elastic earth.

Also eruptions of more viscous volcanoes have been monitored using infra sound sensors. Caused by the different acting physics of ash jets and their associated sound the results are far less convincing than for their low viscous counterpart. Nonetheless, as a diagnostic of whether a volcano is erupting or the seismic signals are just reflecting an intrusion, infra sound recordings might help to discriminate and thus help to improve the early warning especially during bad weather conditions. Care should be taken, however, when installing an infra sound sensor (or sensor array). The reduction of wind noise or other unwanted signals is a difficult task, which might even act in favor of the installation of seismic broad band sensors instead. For details the reader is referred to Arrowsmith et al. (2010) for a very good overview of state

of the art research on seismo-acoustic wavefield and instrumentation.

a)

b)

**Fig. 13.37** Example of a strombolian type explosion recorded with **a)** an infra sound sensor and **b)** a seismometer at Mt. Yasur volcano (Vanuatu). The clear waveform of the infra sound signal is striking and supports the use and model of infra sound signals. However, the comparison with the seismic signal shows that, in this case, the latter already shows a significant amplitude at least 10 s before the onset of the acoustic signal.

### 13.5.2 Ground deformation (D-GPS, P-InSAR, strain, tilt)

Closely related to seismology is the monitoring of the deformation field caused by magma injection and/or hydrothermal pressurization within the volcanoes shallow or deep edifice. Deformation can be considered as an extension of seismology to lower, quasi-static frequencies, closing the gap of observed ground displacement to zero frequency. Modern techniques of monitoring the deformation signals of a restless volcano include borehole tiltmeters and/or strainmeters, electronic distance meter (EDM) and Global Positioning System (GPS) networks as well as airborne or ground based D-InSAR (Differential Synthetic Aperture Radar – Interferometry) measurements. Due to the increasing amount of positioning satellites (GPS, GLONAS) and accuracy, GPS will play an important role in the field of ground deformation monitoring over the coming decades. A relatively novel technique, which promises to have a large impact on the surveillance of active volcanoes are the airborne (airplane or satellite) or ground based differential InSAR measurements (Alba et al., 2008). While the airborne D-InSAR can cover a wide area with just one flight (see Fig. 13.38), the ground based D-InSAR has high repetition rate which makes the application of this technique very attractive during strong changes of the volcanoes edifice (Fig 13.39 for a non-volcanic example). For further reading on this exiting technique the reader is referred to text books of Hein (2004) or Hanssen (2001) and review articles by Bamler et al. 2009) and Bamler and Hartl (1998).

**Fig. 13.38** Composition of differential interferogram and the amplitude image from Stromboli volcano (Italy). The differential interferogram was calculated from the same pair of satellites and an additional SRTM based DEM. Differential phase with the coherence bigger than 0.72 are shown (courtesy: DLR Oberpfaffenhofen, Germany; from: [www.exupery-vfrs.de](http://www.exupery-vfrs.de)).

Fig. 13.39 Non-volcanic example of ground based D-InSAR measurement (Hochstaufen massif, Germany). While the covered area is small in comparison to flight based InSAR, the resolution and repetition frequency can be very high (courtesy: S. Rödelsperger TU Darmstadt, Germany).

A technique which is able to scan fast growing parts of the volcanoes edifice with even higher rates and precision, was originally designed to estimate the speed of particles expelled during strombolian eruptions (e.g. Hort and Seyfried, 1998; Hort et al., 2003). Vöge and Hort (2007) and Vöge et al. (2007) showed how this device, which consists mainly of a modified rain sensor commonly used in meteorology, could be adapted to monitor dome instabilities, which may lead to block and ash flows when this dome collapses. Recently Hort et al (2010) extended this method to also observe slow deformation processes by extracting specific phase information prior to eruptions at Stromboli and Santiaguito volcano.

Regardless what technique is used, the key point of monitoring ground deformation is the assumption that shallow or deep injection of large volumes of magma below a volcano will cause significant deformation of its surface. There were several successful approaches to forecast the 1980 eruption of Mt. St. Helens using deformation information (Murray et al., 2000) and at Hekla volcano, Iceland (Linde et al., 1993). The most recent 2000 eruption of Hekla volcano was accompanied by significant signals recorded by a cluster of strain meters located around the volcano (<http://hraun.vedur.is/ja/englishweb/heklanews.html#strain>). In addition, shortly before the eruption, increasing seismicity and volcanic tremor led to a precise forecast of the eruption (see Fig. 13.40). This can be seen as a perfect example of the complementarity of two different monitoring techniques. In addition there are many papers dealing with correlation between seismic signals and ground deformation at Kilauea volcano (Hawaii; e.g., Tilling et al., 1987)

**Fig. 13.40** The strainmeter data preceding the Hekla 2000 eruption are shown. As a result, three different phases could be defined. Firstly, a conduit was opened between 17:45 to 18:17. Secondly, a reduced rate of expansion of the same conduit at 19:20 could be detected and finally all stations showed an increase when the conduit was fully opened and magma was flowing directly beneath the volcano (courtesy of Icelandic Meteorological Office, <http://hraun.vedur.is/ja/englishweb/heklanews.html#strain>).

A further example of good correlation between measurable deformation and the appearance of seismic signals is known from Suffriere Hill volcano, Montserrat island, West Indies, where Voight et al. (1998) observed a coincidence between several swarms of Hybrid events with cyclic changes in the deformation signals. This coincidence is very important regarding the inversion of source mechanisms of this class of signals. This kind of deformation signal, in conjunction with magma intrusion into the volcanic edifice, is known to be very small and mainly related to the active part of the volcanic dome. At Mt. Merapi several clusters of borehole tiltmeters are installed at the flanks, but only very weak signals have been recorded (Rebscher et al., 2000). In contrast, strong deformation signals are visible at the volcanoes' summit stations (Voight et al., 2000). This might indicate that at Mt. Merapi no large-sized and shallow-situated magma chamber exists and that the volume of ascending magma during typical eruptive phases is small. However, tilt stations at the flanks of Mt. Merapi and other volcanoes with apparently small magmatic activity would be very useful for discrimination between the usual small magma intrusions and possible larger ascending volumes of magma (as in 2010), which will then produce a much more pronounced tilt signal at the flanks of the volcano.

This points to a dilemma of the surveillance of active volcanoes. Some measurement techniques will produce years of just baseline data, which might lead to a reduction of attention (e.g., in equipment maintenance, new investment, number of staff etc.) and instruments. However, if a larger, more threatening eruption is imminent these long-term measurements might be of crucial importance for reliable hazard assessment and risk mitigation.

### 13.5.3 Micro-Gravimetry

The appearance of gravity changes at an active volcano also reflects possible inflation/deflation cycles of magmatic material. There is a complicated interaction between physical and geometric properties (i.e., density, volume, location) of the moving material and height changes caused by the deformation of the surface of a volcano. Therefore, the monitoring of gravity changes is a challenging task that should be carried out with great care. As height changes are a significant component of gravity changes, gravity monitoring should always be combined with high precision leveling (e.g., total stations -electronic distance meters attached to an optical theodolite- or GPS measurements). For a reliable and less ambiguous inversion of the gravity data, a good knowledge of the velocity/density structure of the volcano is needed. Models of the magmatic system from gravity data should be regarded with caution, unless the conclusions are also supported by other independent observations.

### 13.5.4 Gas monitoring

Another important parameter preceding a volcanic eruption is the volume, velocity, temperature and composition of the emitted gas from a volcanic vent or fumarole. Volatiles and released gases are seen as the most important driving forces for both an eruption and the source of volcanic signals (e.g., explosion quakes, LF, MP, volcanic tremor; Schick, 1988; Vergnolle and Jaupart, 1990). Different techniques of gas sampling are in use, ranging from routinely collected gas samples in a weekly or monthly manner to a continuous analysis (every 20 - 30 min) of the emitted gas using a gas-chromatograph (Zimmer and Erzinger, 2003). For example high sampling rate in continuous data at Mt. Merapi revealed surprisingly short period pulsations (with a duration of 3-5 hours, see Fig. 13.41) in the water to carbon-dioxide ratio as well as in the temperature of a fumarole (Zimmer and Erzinger, 2003).

**Fig. 13.41** Variation of the gas composition at one of Mt. Merapi's fumaroles. The gas is automatically analyzed approximately every 30 min using a gas-chromatograph. The analysis shows a fast changing composition of the gas with a period of roughly 5 hr. This special fumarol field (Woro) was altered/destroyed during the 2006 and 2010 eruptions of Mt. Merapi (courtesy of M. Zimmer, GFZ-Potsdam).

However, no significant correlation between this pulsation and the related seismicity could be found. The rhythms in this pulsating gas source only changed when the number of very shallow MP-events also increased. This lack of correlation between fast sampled gas data and seismic signals at Mt. Merapi might be caused by the our imperfect knowledge of how to parameterize the seismicity and the gas composition, respectively. Several case studies of changes in the chemical composition of fumarolic gases including descriptions of the accompanying seismicity and ground deformation is given by Martini (1996).

Many other papers deal with the long-term variations of gas prior to a volcanic eruption, which makes this technique a useful tool for long term monitoring (e.g., Stix and Gaonac'h, 2000).

Sulfur dioxide measurements from satellites make it possible to monitor volcanic activity and eruptions on much larger, even global scales. E.g., the Global Ozone Monitoring Experiment (GOME-2; carried by the MetOp-A satellite launched in 2006) provides, next to other gases, SO<sub>2</sub> columns with a global coverage within 1.5 days and a spatial resolution of 40 x 80 km (Fig. 13.42)

**Fig. 13.42** Space-based observations allow near-real time detection of volcanic activity: SO<sub>2</sub> columns from GOME-2 as overlay on a MODIS (Moderate Resolution Imaging Spectroradiometer) imagery of Mt. Etna volcano, Italy (courtesy: DLR Oberpfaffenhofen; from: [www.exupery-vfrs.de](http://www.exupery-vfrs.de)).

The satellite based volcanic SO<sub>2</sub> emissions are determined from solar backscatter measurements in the ultra-violet spectral range. In so doing, the Differential Optical Absorption Spectroscopy (DOAS) is applied, a technique, which may also be used as a ground based installation. The ground based counterpart has again much higher repeat rates and is thus a very valuable technique when a volcano shows first signs of unrest. The main goal of the satellite based technique is to monitor and forecast the dispersion of volcanic plumes up to 3 days and to attribute the detected SO<sub>2</sub> to a particular volcano. The final goal is than to facilitate a global warning service using SO<sub>2</sub> data. Over the past couple of years DOAS measurements are starting to be replaced by so called SO<sub>2</sub> cameras (see e.g. Bluth et al, 2007; Mori and Burton, 2006), at least for the determination of the SO<sub>2</sub> concentrations. They allow a 2D measurement at a rather high temporal resolution (up to 10Hz).

### **13.5.5 Thermal and video recordings**

Monitoring of volcanic activity using radiometer or other imaging systems has been increasingly used over at least the last 25 years from space-borne or ground based remote sensing infrared sensors. The primary goal is the detection and analysis of volcanic hot spots and plumes at remote volcanoes. Modern sensors are now capable of resolving thermal anomalies even allowing the detection and monitoring of smaller effusive events. Over the last decade most observation from space of volcanic eruptions were carried out using data from AVHRR, GOES, MODIS, ASTER, BIRD, and Landsat-7 / ETM system. The different systems differ mainly in their spatial resolution ranging from 8×8 km for 6.47–7.02 μm band on GOES down to 15×15 m pixels for the VNIR bands on ASTER. Also the repeat times varies also strongly, with geostationary systems sending images every 15–30 min in contrast to the ASTER/MODIS system with repeat cycles of 16.5 days. At some volcanoes stationary, ground based infrared cameras proved to be useful to monitor changes in the volcanic system. Meanwhile cheap(er) and less sensitive devices are on the market which makes a remote installation at a sight with visibility to active vents possible (e.g., Stromboli, Popocatepetel etc.).

A lot more material can be found on the web page [www.exupery-vfrs.de](http://www.exupery-vfrs.de).

### **13.5.6 Meteorological parameters**

While not directly linked to the eruptive behavior of a volcano, monitoring meteorological conditions is important for the proper interpretation of observed parameters as well as for the anticipation of possible triggering of volcanic activity. Lahars, i.e., volcanic debris flow, are often triggered by heavy rainfall, which additionally weakens the unconsolidated volcanic material. At Mt. Merapi, small-size gravitational dome collapses take place more frequently during the tropical rainy season.

The influence of meteorological conditions on the installed monitoring equipment is manifold. Barometric pressure and temperature changes could cause severe disturbances on installed broadband seismometers and tiltmeters, respectively. While these influences can be reduced by proper installation of the sensors (see Section 13.6), it is never completely removed. Spectral analysis of both meteorological and surveillance parameters may help to identify possible disturbances of the installed sensors. As mentioned before, rainfall may trigger volcanic as well as seismic activity. A good monitoring station will therefore also have

a continuously recording rain gauge.

In order to better judge the influence of meteorological (and also tidal) effects on the sensors and/or the volcanic activity, continuous long-term meteorological recordings are needed. Frankly speaking this is a difficult and sometimes impossible task because of the harsh environments at many active volcanoes. However, the continuity of such measurement are among the most important functions of a volcano observatory.

## **13.6 Technical considerations**

In this chapter, some baseline information regarding the technical design of seismic surveillance network is given.

### **13.6.1 Site and vault**

After selecting a possible site (see Section 3.1) for a seismic station or a seismic array, significant care should be taken to protect the sensor from meteorological and other external effects. In Fig. 13.43a, a sketch of a possible installation scheme is shown. If a broadband sensor is to be deployed, even more care must be taken to protect this sensitive sensor from temperature and barometric pressure influences (see Chapter 5, Section 5.5 and Chapter 7, Section 7.4). Installations cover the sensor completely in sand in order to avoid instrument near air convection, which may lead to long period noise. Please inspect your instrument manual if this method will work for your instrument.

The weather conditions at volcanoes at even moderate altitudes can be very rough and rapidly changing. Protection against rain and lightning is the most important task when constructing a seismic station. All equipment should be placed in water tight casings, however, a water outlet should always be present. Most of the time it is harder to remove the water condensate from the vault than protect it against meteoric water.

Lightning protection is the most important and, unfortunately, the most difficult problem to solve (see Chapter 7, Section 7.4.2.5). Commonly, volcanoes have high resistivity surface layers (ash, lapilli etc.), making a proper grounding of the instruments nearly impossible. One of the optimal techniques to protect the equipment against lightning damage is to install a tower at the vicinity of the station with a mounted copper spire on top. The tower should be grounded as much as possible and be connected entirely with the ground of power-sensitive equipment. Furthermore, lightning protectors should be placed in front of any equipment to reduce the effect of high-voltage bursts (see Fig. 13.43b-c). Long cable runs should be avoided or changed to fibre optics. Using fibre optic cables for signal transmission has also the advantage that they are insensitive to electro-magnetic effects, which sometimes cause spike bursts on the transmitted signals.

**Fig. 13.43** **a)** sketch of a seismometer vault. The sensor should be placed in a water tight casing which is placed firmly on a concrete basement. In order to isolate the sensor from temperature and pressure changes due to air turbulences, the void space should be completely filled with insulating rubber foam or similar (see Chapter 7, Section 7.4.2). **b)** shows a lightning tower installed at Mt. Merapi, while **c)** shows additional lightning protectors for all sensitive equipment. The copper plate and all external devices (photo-voltaic modules) should be connected to the lightning tower.

### 13.6.2 Sensors and digitizers

Because the seismic signals produced by an active volcano cover a wide dynamic range the choice of the digitizer, i.e., the required dynamic range, should be carefully evaluated. Modern digitizers will sample the analog seismometer output with 24 bit resolution which results in a dynamic range of roughly 136 dB (depending on the sampling rate). A 16 bit A/D converter would usually be sufficient, but eruptive phases with various large amplitude signals will then saturate the digitizers' dynamic range (e.g., pyroclastic density flows, big explosions etc.). So called "gain-ranging" (i.e., the pre-amplification will be lowered if the signal is getting stronger) should be avoided because it will result in lower resolution and might mask small but important signals. Best suited are digitizers which sample with 24 bit

resolution but store the data depending on the recorded peak amplitude (i.e., 8 bits are stored if the signals are small and the activity is low, 16 bits when the activity is increasing and 32 bits if high activity occurs and the full 24 bit range is used).

If a network of seismic sensors is planned, several three-component short-period instruments (i.e., with 1 Hz corner frequency) will be sufficient (see Section 13.3.2). If the near-crater range is accessible, installing one or two broadband stations (i.e., 0.00833 to 0.05 Hz corner frequency) is a good choice. If large ( $M > 4$ ) earthquakes from an active volcano flank or nearby fault or subduction zone are possible, some broadband stations are preferred.

If an array or a network of arrays is to be installed, a mixture of three-component broadband and short-period one-component seismometers will be sufficient (especially when considering that there is no straight forward technique available which involves directly 3D seismic array data). A possible four station array would consist of a central three component station while the three satellite stations are equipped with vertical component sensors only.

### **13.6.3 Digital telemetry and satellite communication**

Most of today's established monitoring networks at volcanoes are designed for transmitting the data "on-line" to a central data center, generally the local volcano observatory. This might be the main technical difference between a short-term seismological experiment and the long-term monitoring of a volcano. From experience worldwide, establishing a reliable radio line is a difficult and time consuming task, which also is subject to changes when new telecommunication facilities are constructed nearby and possibly worsen the data communication.

There are large differences between analog and digital radio transmission regarding data rate, dynamic range and sites to be selected and distance ranges to be covered. If a high resolution is required (e.g., using a 24 or 16 bit A/D converter at the sensor), the only way to exploit the full bandwidth of data is to transmit the signals with a digital radio modem. Meanwhile, several companies offer spread-spectrum modems which transmit in the frequency range of roughly 1 GHz and 2 GHz, respectively. The big advantage of these digital modems is the high data throughput (115,200 baud) and the low power consumption (transmitting power roughly 1 Watt). The high transmission frequency, however, is the main drawback of the digital radios. Commonly, the station and the data center must be in direct line of sight, with no hills, trees or other obstacles between them. This limitation should also be kept in mind when selecting a suitable seismic station site. The problem of obstacles can be circumvented when installing several repeaters on the way to the data center. Even so, the network design depends on intended radio lines (see also Chapter 7, Section 7.3 and Information Sheet IS 8.2).

A disadvantage of analog radio communication is the limited dynamic range and data throughput (usually below 38,400 baud). Most of the installed analog radio systems are barely able to transmit 12 bit and, therefore, the signals must be bandpass filtered (e.g., 1 - 20 Hz) before transmitting it. This is not acceptable when installing a broadband sensor. However, the radios are cheap and the typical frequency bands (100 MHz or 400 MHz) will enable a solid radio link even when the stations are slightly "out of sight".

Wireless LAN technology lately took over a large share in the communication business.

While in many countries the maximum applicable power output is restricted to 100 mW an intelligent use of different antennas for transmitting (low gain) and receiving (high gain) will allow distances of up to 10 km without the use of a repeater.

Even more suited for a communication network at active volcanoes are so called self organizing meshes. These ad hoc networks are able to organize their communication paths by themselves just by giving a central device the IP number of the transmitting station) see Fig. 13.44). If one of the nodes (transmitters) is lost, the network will re-organize itself to reach the stations by a different path. The drawback, however, is the rather complicated setting of the network as well as that potential station sites are chosen based on transmission properties rather than geological/geophysical evidences.

**Fig. 13.44** Schematic principle of operation of a Wireless-LAN mesh. In case one of the nodes is not operational the data from a particular station is transmitted using a different path to the data center (courtesy: M. Hort; from: [www.exupery-vfrs.de](http://www.exupery-vfrs.de))

Meanwhile also many different satellite communication devices (V-SAT, Sky-DSL) are available. Due to the still high power consumption and rather sensitive equipment the use of these devices is restricted to certain points within the network (e.g., connection of the observatory to the international community; special node of high throughput).

### 13.6.4 Power considerations

Most of the stations will be remote and no access to a power network will exist. Therefore, the first step is to calculate the expected power consumption of the seismic station. It strongly depends on the kind of digitizer and sensor used, whether the data are transmitted by radio or not and which options for local data storage are desired. Therefore the power consumption of the field equipment should be extensively tested in the lab before constructing the power supply at the site and deploying the instruments. Never trust the optimistic specifications given by the manufacturer!

Most likely the power will be delivered by photo-voltaic (PV) modules, where a variety of different systems is available. All components of a monitoring installation must fit together, including the capacity of batteries and solar charger. Care must be taken, when estimating the amount of solar-modules needed to supply the stations. As a rule of thumb, 10% of the nominal maximum voltage will be supplied by the panels on average (i.e., using a 50 Watt module just 5 W are available on average). Voltage will typically decrease when the panels are installed high up in the mountains. Clouds, snow or ashfall may further reduce the effective power output (i.e., 5% or even less). This significantly increases the number of PV-modules required. To give an example, let the station consume at least 20 W (including radio, some digitizers, SCSI disks for local storage etc.), you will need 400 W panel power in the worst case which is 8 x 50 W panels at this station!

New developments in manufacturing solar-cells increase the efficiency of PV-modules. Especially the CIS technology (Copper, Indium and Selen) in combination with different alignment of the cells makes them more robust against partial shadowing and more efficient in diffusive light condition. The higher costs per panel are balanced by fewer numbers of panels needed to supply power for the monitoring station.

Also the capacity of the battery must be adequate in case no solar power is produced. However, the battery should not be too big in capacity as the PV-modules must be able to recharge the battery in sufficient time. Whenever possible, alternative power sources should be used, such as robust wind generators. It should be kept in mind, however, that a nearby wind generator might increase the noise of a seismic sensor. In case the station is located near running water, a small hydro-power engine could be a good alternative.

A novel and promising approach in building independent power supply which also produce enough power to feed even sophisticated but high power consuming radar devices or satellite dishes originates from the development of fuel cells. Meanwhile there are several different systems of portable fuel cells available. The fuels ranges from classical hydrogen to methanol based systems, which are cheaper and also carry a higher energy to weight factor. Combining PV modules together with fuel cells reduces the usage of fuel by guaranteeing the unbroken power supply. We note however that methanol is a hazardous substance and sometimes difficult to transport on ships and planes.

Care should be taken in the choice of the (programmable) solar charger and the batteries used. Currently Absorbed Glass Mat (AGM) batteries are most suitable for application at a remote site. They are lighter and more easily charged and discharged than common lead-gel batteries but also completely sealed and thus maintenance free. In future lithium air batteries might play an important role in solving the current problems of running monitoring equipment at remote areas.

### 13.6.5 Data center

All data streams, including those from monitoring techniques in addition to seismic, should be collected, stored and archived in a central facility. In the age of high-performance low-cost PC's, few standard computers will be sufficient to satisfy all needs of data collection, backup systems, automatic and visual analysis. Because continuous recording of all relevant signals is preferred over triggered data, a good backup strategy is crucial for getting complete and long-term data. Continuous recording is indispensable for improving our knowledge about volcanic activity, the underlying physical mechanisms and the relevant parameters to be observed when aiming at improving eruption forecasting. With the advent of DVD disks and CD-ROMS a good solution would be to write images of data sets onto one of these media in a daily or regular manner. CD-ROMS in particular assure a good data safety to price ratio.

Much public domain software is available for either automatic (e.g., EARTHWORM; Johnson et al., 1995) or interactive analysis (SeismicHandler, SAC, IASPEI-Software, PITSA/GIANT). The Orfeus homepage is a good starting point when looking for suitable software and for further contacts ([www.orfeus-eu.org](http://www.orfeus-eu.org))

A very promising new application in the field of “real-time” analysis is distributed as seiscomp3 by the German Research Centre for Geosciences (GFZ-Potsdam). The main advantages are the new design concepts (C++; Python plugins etc) as well as an up-to-date graphical user interface for interactive analysis. In contrast to EARTHWORM, seiscomp3 is directly connected to a SQL-database which can store the analyzed (seismic) event data. The major drawback of this new package lies in the strong focus on seismic real time analysis, which is difficult to change.

A different strategy was chosen during the development of ObsPy ([www.obspy.org](http://www.obspy.org)) and SeisHub ([www.seishub.org](http://www.seishub.org)), which are not real-time packages but form a “near-real-time” system adapted for the need of small to medium sized observatories. All source code parts are completely licensed under GNU and may be altered and changed according to the need of the users.

Obspy/SeisHub together with EARTHWORM or seiscomp3 may serve as a good, flexible and easy extendable software solution for a volcano data center.

A special requirement of the data center is the availability of an “uninterruptable power supply” (UPS) to guarantee a loss-less data collection even if the power line of the observatory is broken. Depending on the quality of the power network, a generator could be a good solution to bypass blackouts which may last several hours.

Establishing a “quick-response” volcano observatory during a volcanic crisis of a long-dormant volcano need additional equipment and design criteria of the monitoring network to be deployed. All equipment, including the data center facilities, should be light weighted, robustly made and should have low power consumption. These demands very likely lead to down-grades in resolution and data through-put. A comprehensive description of one realization of mobile monitoring network, the *Mobile Volcano-Monitoring System*, is given by Murray et al. (1996).

Meanwhile several different new applications exist which are designed to react as quickly as possible to new volcanic crisis. An early European initiative EMEWS (European Mobile Early Warning System) was formed in order to define European standards in mobile volcano alarm systems.

A more national approach, which tries to include all possible sets of monitoring parameters, environmental parameters and network metadata is the Exupery-Volcano Fast Response System (VFRS; [www.exupery-vfrs.de](http://www.exupery-vfrs.de)). The goal of this initiative is to record and store all volcano relevant information in a newly developed database ([www.seishub.org](http://www.seishub.org)), to find new strategies of volcanic monitoring (e.g., ground base InSAR; space borne surveillance of active volcanoes) and to aid or guide the local observers and/or decision maker by creating a data visualization system based on geographic information (GIS) and the estimated monitoring parameters (via EARTHWORM/seiscomp3 – ObsPy/SeisHub). The resulting GIS is also freely available (executable as well as source code) at [www.exupery-vfrs.de](http://www.exupery-vfrs.de). Fig. 13.45 gives a snapshot of possible applications. One of the design criteria for the GIS was its platform independence and easy handling.

**Fig. 13.45** Snapshot of the Exupery GIS. The browser-based application can include ground-based parameter sets and data as well as display 2D InSAR sections and 3D models.

The more and more common storage of multi-parameter data together with environmental data makes the application of “data mining” much more attractive. First steps in this direction are the application of automatic alert level systems based on Bayesian Belief Networks (BBN), which were introduced in volcanology by Aspinall et al. (2003) and Marzocchi et al. (2008). Fig. 13.46 shows the graphical network representation of a BBN build in into the Exupery VFRS. The output of this network consists of a simple alert level estimation which

should only guide the local authorities in their decision. One of the key advantages of this probabilistic belief networks lies in the specification of uncertainties of parameters which lead to a decision. With the interactive tools now available (e.g., GeNie, <http://genie.sis.pitt.edu>) and open source library (smile, <http://genie.sis.pitt.edu>) an observer is able to compute the level of probability once a BBN has been constructed and interactively change the BBN output by putting weights on different nodes, when additional information (e.g., field observation, “expert knowledge”) is at hand.

**Fig. 13.46** Bayesian Belief Network used for automatic alert level estimation within the Exupery VFRS. This BBN is a modified version of a graphical network designed by Aspinall (courtesy of the author, from: [www.exupery-vfrs.de](http://www.exupery-vfrs.de)).

## Acknowledgments

I am grateful to the reviewers F. Klein, R. Scarpa and R. Tilling for their helpful comments and corrections to the first version, M. Hort and C. Bean for the revised manuscript, which improved the text significantly. I also thank P. Bormann for additional editing of this chapter. Without his continuous effort and labor this chapter never would have been realized. Furthermore leaving the figures and seismograms of E. Gottschämmer, S. Falsaperla, S. McNutt and M. Ohrnberger are highly appreciated. A lot material was taken from the Exupery project homepage ([www.exupery-vfrs.de](http://www.exupery-vfrs.de)).

### 14.1 Introduction

The distribution of damages due to recent earthquakes have shown that the effects of local geology on ground shaking represent an important factor in engineering seismology. Figure 14.1, schematically shows that when an earthquake occurs, waves generated at the source propagate through the Earth (generally with decreasing amplitude with distance). When two

nearby sites are located on the top of different materials, the ground shaking they experience can be very different. These differences might be very important considering that (1) buildings can react to the input ground motion emphasising shaking depending on their frequency of oscillation, and (2) that they can even redistribute energy back to the Earth due to scattering and diffraction of seismic waves when interacting with their foundations and acting as a source while shaking.

**Fig. 14.1** Simplified representation showing seismic wave propagation after an earthquake. Blue triangles indicate stations located over different near surface geological material (S1 on a rock site and S2 on soft quaternary material) experiencing different ground motion.

The modification of the ground motion due to the Earth structure below the site can be related to different factors (e.g., Safak, 2001) (Fig. 14.2). In general, the main factor is the impedance contrast (see Chapter 2, subsection 2.5.4.1) between the soft sedimentary cover (with low density  $\rho_1$  and wave propagation velocity  $v_1$ ) and the bedrock (with high density  $\rho_2$  and wave propagation velocity  $v_2$ ). The impedance contrast  $c=(v_2 \rho_2)/(v_1 \rho_1)$  determines how strongly the waves at particular frequencies (the fundamental resonance frequency and the higher harmonics) are multi-reflected within the soft layer, thus trapping the wave energy within the layer (1-D effect). Quantitatively, and under the simplified assumption of vertical propagation of S waves, the modulus of the 1-D site amplification function  $H(f)$  can be described by the following relation:

$$|H(f)| = \left( \frac{(1+r)^2}{1+2r \cos(4\pi f \tau) + r^2} \right)^{\frac{1}{2}}, \quad (14.1)$$

where  $\tau$  is the travel time of the S waves in the soft sedimentary layer and  $r=(\rho_2 v_2 - \rho_1 v_1)/(\rho_2 v_2 + \rho_1 v_1)$  is the reflection coefficient that is clearly related to the impedance contrast  $c$ . The maximum of  $H(f)$  is obtained when  $\cos(4\pi f \tau)$  is equal to -1 that is when  $f = 1/(4\tau)$ . This value of  $f$  is defined as the fundamental resonance frequency  $f_0$ . From the previous

consideration it follows the well know relationship  $f_0 = v_1/(4h_1)$  where  $h_1$  is the thickness of the soft sedimentary layer.

The site response (here represented by the shape of the Fourier spectra amplitude ratio between the surface recording and the input ground motion at the bedrock) is then determined by the S-wave velocity and the thickness of the sedimentary cover layer, which determine the frequencies that are affected by amplification, while the impedance contrast controls the amplification level. The quality factor  $Q$  (see Chapter 2, subsection 2.5.4.2) in the soft sedimentary cover influences the decay of the site response with increasing frequency.

Other effects like focusing, diffraction of body waves at the edges of sedimentary basins (2-D or 3-D effects) and scattering should also be taken into account. Sites located on pronounced (with respect to wavelength) topographic relief can also suffer significant amplification of ground motion. Importantly, in the case of strong ground motion the soil may behave non-linearly. In particular, the frequency of resonance of soil tends then to decrease and the damping to increase. Due to pore pressure increase and dilatancy high frequency spikes in ground motion are occasionally observed (Bonilla et al., 2005).

Thus, assessing the amplification/deamplification and lengthening of seismic ground motion due to superficial geology is of primary importance for earthquake microzonation studies. In the past few decades, the evaluation of site effects has attracted growing attention. In particular, due to the increasing importance of reliable seismic hazard assessment in large urban areas (e.g., Istanbul, Santiago de Chile), large efforts has been devoted to the development of tools for site effect estimation that allow large areas to be covered at limited costs.

**Fig. 14.2** Local features and effects that can modify the ground motion: 1) Resonance due to impedance contrasts; 2) Focusing due to subsurface topography; 3) Body waves converted to surface waves; 4) Water content; 5) Heterogeneity of the Earth medium; 6) Surface topography (Safak, 2001).

Site effects can be estimated by means of numerical simulations and experimental methods. The former range from simple 1-D numerical calculations to methods that consider complex phenomena and model geometry. In general, the experimental methods are subdivided into two categories: reference site and non-reference site techniques (see, e.g., Bard, 1995).

Borcherdt (1970) was the first to propose the reference site method (RSM) that consists in comparing records at nearby sites, using one as the reference site. It is assumed that records from the reference site (in general a station installed on outcropping hard rock) contain the same source and propagation effects as records from the other sites. Therefore, differences observed between the sites are explained as being due to local site effects. This method is generally applicable only to data from dense, local station deployments of arrays (see also Chapter 9 of this Manual). Andrews (1986) extended this method to large networks. He proposed to separate the contribution of the path, the source, and the site by means of an inversion scheme termed the generalized inversion technique (GIT). Since in general the site amplification at a reference (hard rock) site is set to unity, this approach provides results analogous to those obtained by the RSM method.

However, the major drawback of these methods is that a suitable reference site may not always be available (Steidl et al., 1996), because also rock sites might have their own response. Furthermore, being rock site often located on hills, topographic effects (due to the geometry of the Earth surface, the weathering of the shallow rock layers etc.) cannot be easily ruled out. In order to overcome this disadvantage, non-reference site techniques such as the horizontal-to-vertical (H/V) spectral ratio method are widely used, although they provide only partial information about the site response. Nogoshi and Igarashi (1970) first introduced this technique, but Nakamura (1989) developed it further as a tool for estimating the site response of S waves. Originally, it was proposed for interpreting ambient seismic noise measurements (NHV). Lermo and Chavez-Garcia (1993) applied the H/V technique to the S waves of earthquake recordings (EHV) and developed a theoretical background for the technique using numerical modelling of SV waves.

The comparison of site responses obtained with reference and non-reference site techniques (e.g. Field and Jacob, 1995; Bonilla et al., 1997; Riepl et al., 1998; Triantafyllidis et al., 1999; Parolai et al., 2000; 2001a; 2004) has shown that RSM and EHV usually provide site responses with similar shapes when the S-wave part of the seismogram is used. The fundamental resonance frequency of a site is consistently estimated by both methods. However, they can provide different levels of amplification, in particular at frequencies higher than the fundamental one. Parolai and Richwalski (2004) showed, by means of numerical simulations, that differences between the RSM and the EHV results are caused by the effect of waves that have been converted at the bedrock depth and are included in the analyzed record time windows. In particular, due to the S-to-P conversion, a deamplification at frequencies higher than the fundamental one is observed in the EHV ratio for S-waves.

NHV has been shown to provide (e.g., Haghshenas et al., 2008) a good estimate of the fundamental resonance frequency of the S waves, but it underestimates the level of amplification with respect to GIT and RSM. Also, by using the P-wave part of the seismograms, the RSM and EHV methods have been found to provide consistent results only in some cases.

In the following, the development, testing and application of techniques for site effect estimation is outlined with special attention to studies carried out in large urban areas. First, the most popular methods for site effects investigation in urban area are described. Second, the use of seismic noise as an optimal tool for investigating the subsoil structure in urban areas will be illustrated. Not described are here other subsoil investigation methods based on active sources such as SASW (Stokoe et al., 1994), MASW (Park et al., 1999) and REMI (Louie 2001). Finally, based on the experience gained in the application of empirical

techniques to large urban areas, recommendations are given on how to estimate best site effects in different environments.

The intention of this chapter is to provide an overview of the work carried out during past and ongoing activities, with an emphasis on personal practical experience. Thus, this chapter may not appear to some readers to be a comprehensive review of the huge amount of significant literature that has been published in this field. If so, the author apologises for this.

## **14.2 Empirical methods (earthquake based)**

The empirical methods can be classified into two categories: reference site and non reference site techniques. While the former requires the availability of a station installed on a hard rock outcrop (the reference site), the latter assumes that one of the components of the ground motion (generally the vertical one) provides the input ground motion at the bedrock (see for more details 14.2.2). This assumption is mainly based on the empirical observation of similar amplitude of the horizontal and vertical component of ground motion in borehole recordings and on the presumed lack of amplification of the latter one.

### **14.2.1 Reference site techniques**

Reference site techniques can be used by taking the direct spectral ratio of the same component of ground motion recorded at two nearby stations (Standard Spectral Ratio SSR) (Fig. 14.3) or by deriving the site response via an inversion procedure (generalized inversion technique GIT). Generally, S-wave or P-wave signal windows are extracted from the seismograms starting before the phase arrival and ending either when a certain amount of energy is reached or after a pre-fixed amount of seconds. The selected time series are corrected for the instrumental response and the trend in the data. The two horizontal components can be analysed separately or combined. The vectorial sum or the root means square of the two horizontal components is often used in the analysis. Both ends of the selected signal window are tapered (for example with 5% cosine functions) and then the Fast Fourier Transform (FFT) calculated. Tapering is necessary to suppress spectral leakage before calculating the FFT (see IS 14.1). The resulting spectra are smoothed by using running time windows (preferably equally spaced on a logarithmic scale). The analyses are performed considering frequencies with a signal-to-noise (SNR) ratio larger than a certain threshold (generally at least 3), estimated by considering the Fast Fourier Transform (FFT) of a noise window as wide as the signal window.

**Fig. 14.3** Schematic description of the Reference Site Method. Blue triangles represent hypothetical seismological stations recording three component ground motion (directions are schematically indicated by the arrows).

#### 14.2.1.1 Standard Spectral Ratio method (SSR)

The Standard Spectral Ratio technique (SSR) consists of comparing records at nearby sites, using one as the reference site (Figure 14. 3). It is assumed that records from the reference site (in general a station installed on outcropping hard bedrock) contain the same source and propagation effects as records from the other sites that is:

$$\frac{U_{ij}(f, r)}{U_{ik}(f, r)} = \frac{S_i(f)Z(f)_j A_{ij}(f, r)}{S_i(f)Z(f)_k A_{ik}(f, r)} \quad (14.2)$$

where,  $U_{ij}(f, r)$  is the spectral amplitude of the ground motion observed at a recording site  $j$  for an event  $i$ ,  $S_i(f)$  is the source function,  $Z_j(f)$  is the site response,  $A_{ij}(f, r)$  is a function accounting for attenuation that includes the effect of geometrical spreading, intrinsic and scattering quality factor.  $f$  is the frequency,  $r$  the hypocentral distance and  $k$  indicates the reference station. Note, that similarly to what is schematically indicated in Figure 14.1, the ground motion recorded at one station is considered as the convolution of three terms, specifically the source  $S_i(f)$ , the path  $A_{ij}(f, r)$  and site response  $Z_j(f)$ . If the stations are nearby and the reference station is not affected by site effects, then  $Z_k = 1$  and  $A_{ij}(f, r) \approx A_{ik}(f, r)$ . Thus, the spectral ratio directly provides the site response at the non-reference stations. The major drawback of this method is that rock stations may also have their own response. Furthermore, a good reference site might be located too faraway from the target site therefore not allowing assuming similarity in the wave paths towards the two stations.

#### 14.2.1.2 Generalized inversion technique (GIT)

The natural logarithm of the spectral amplitude  $U_{ij}(f, r)$ , observed at a recording site  $j$  for an event  $i$ , can be represented by:

$$\ln U_{ij}(f, r) = \ln S_i(f) + \ln Z(f)_j + \ln A_{ij}(f, r), \quad (14.3)$$

where, according to equation (14.2),  $S_i(f)$  is the source function,  $Z_j(f)$  is the site response,  $A_{ij}(f, r)$  is a function accounting for attenuation,  $f$  is the frequency and  $r$  the hypocentral distance.

For all events and stations, equation (14.3) describes a linear system of the form  $\mathbf{Ax} = \mathbf{b}$ , which can be solved by using suitable inversion algorithms. The inversion can even be performed in two steps following the procedure of Castro et al. (1990). In the first step, the inversion is carried out to separate the source and attenuation effects without introducing any parametric model to describe the attenuation term  $A_{ij}(f,r)$ . The trade-off between attenuation and source is resolved by requiring that attenuation assumes an a priori chosen value at a given distance, irrespective of frequency. This assumption is justified by the small effect that the total attenuation (intrinsic and scattering) has on the decay of the wavefield amplitude at short distances. In the second step the inversion is carried out for the source and site functions, using the observed data that have been corrected for the attenuation. The undetermined degree of freedom of the second inversion is resolved by constraining the logarithm of the site amplification of the reference station (generally a rock site) to 0, irrespective of frequency. In cases when a reference site cannot be identified (for example by a simple horizontal-to-vertical spectral ratio of earthquake data; see next section 14.2.2) the average response of the whole network is constrained to 0. Although this restriction affects the absolute value of the single site functions, it does not affect the source functions.

Parolai et al., (2000) applied the GIT technique to investigate the site response at stations of a small urban network, while Bindi et al., (2009) used the GIT for estimating 2-D or 3-D site effects in a small basin. Recent examples of application of the GIT approach include Moya and Irikura (2003), who performed the inversion using a reference event instead of a reference site, Oth et al. (2008 and 2009), who applied the technique to an area where a simple parameterization of attenuation was not possible, and Drouet et al., (2008), who introduced a non-linear inversion scheme, although this is valid only under assumptions made on the source spectral shape.

### **14.2.2 Non-reference site techniques: H/V spectral ratio of earthquake data (EHV)**

Non-reference site techniques allow to avoid the requirement of having a good hard rock reference station, either by making the assumption that the vertical component of the ground motion is not affected by amplification and that it is similar to the horizontal component at the bedrock (when earthquake recordings are used), or using seismic noise recordings generally dominated by surface waves (Fig. 14.4). While the assumption of the former cannot be true for frequencies higher than the fundamental one (Parolai and Richwalski, 2004), the second suffers from the lack of correlation between the estimated amplification level and that measured by earthquake data analysis. However, both methods can satisfactorily estimate the fundamental resonance frequency of a site.

**Fig. 14.4** Schematic description of the EHV method. The blue triangle represents a hypothetical seismological station recording three-component ground motion (directions are schematically indicated by the arrows). One horizontal component and the vertical component recordings are shown.

The EHV spectral ratio technique was introduced by Langston (1979) as a method to determine crustal and upper-mantle structure from teleseismic recordings. The basic assumption of the method is that the vertical component of motion is not influenced by the local structure, whereas the horizontal components contain the P-to-S conversions due to the geology underlying the station. Therefore, by deconvolving the vertical component from the horizontal, one could estimate the site response. The deconvolution is generally carried out by dividing the Fourier spectra of the horizontal component by the vertical one. However, the deconvolution operation is applied to data corrupted by noise and therefore, since this problem is ill-conditioned, small errors in the data could lead to solutions unacceptable from a physical point of view. Several regularization techniques are available to avoid artifacts in the results. The most common practice, although it is not properly a regularization approach, is to carry out the spectral ratio after having smoothed the spectra. The technique has been applied in many studies (e.g., Lermo and Chavez-Garcia, 1993; Field and Jacob, 1995; Lachet et al., 1996; Bonilla et al., 1997; Parolai et al., 2004; Parolai and Richwalski, 2004). In general, it was found that H/V ratios for S waves reveal the overall frequency dependence of the site response, even if the level of amplification, especially at frequencies higher than the fundamental one, can be different from that obtained by SSR analysis.

### 14.2.3 Vertical array data analysis

The increasing number of observations over the last few decades has greatly contributed towards the understanding of strong-motion site effects by the engineering and seismological communities, leading to advancements in the state of knowledge and modelling of in situ sediment response (Field et al., 1997). Nonetheless, finer resolution and more effective representation of the involved physics in the near surface medium require a good estimate of the input motion and of wave propagation in shallow layers. For this, by far, the best source of information is provided by downhole arrays, consisting of accelerometers recording ground motion at different depths and on the surface of the same site (see Chapter 7, Sub-chapter 7.4.6 on borehole strong-motion array installations).

Downhole measurements are a valuable complement to in situ and laboratory geotechnical investigation techniques. Indeed, they provide critical constraints for both the interpretation methods for surface observations as well as information on the real material behaviour and overall site response over a wide range of loading conditions (Assimaki et al., 2008). The amount and quality of information from downhole arrays in seismically active areas is the key for improving our understanding of in situ soil behaviour, assessing the modelling and parametric uncertainties associated with employed methodologies for strong-motion site-response analysis, and for shallow geological investigations.

Several methods have been proposed for estimating wave propagation velocity and damping from boreholes recordings. Amongst others, Trampert et al., (1993), van Vossen et al., (2004) and van Vossen et al., (2005), focused their attention on the SH phase propagation, while Mehta et al. (2007a; 2007b), starting from the similarity between deconvolution and the cross correlation tool used in seismic interferometry (e.g., Lobkins and Weaver 2001; Schuster et al., 2004; Shapiro and Campillo 2004; Snieder et al., 2006; Halliday and Curtis, 2008a), showed that the deconvolution of waveforms recorded by a vertical array can provide useful insight into the wavefield propagation in the uppermost crustal layers,. Although the use of the Fourier spectra amplitude ratio (uphole to downhole or with a reference station) is well known in engineering seismology (e.g., Safak, 1997), the deconvolution of seismograms (retaining information about phase) and their interpretation in the time domain has found few applications (Trampert et al., 1993; van Vossen et al., 2004; van Vossen et al., 2005). Assimaki et al.,(2008) proposed an inversion procedure that aims at estimating the best borehole model in term of shear wave velocity, attenuation and density, by optimizing the correlation between observed and synthetic seismograms. Parolai et al. (2009) showed by using a deconvolution approach that the wave propagation in the shallowest layer can be imaged independently on the chosen signal window and that down-going waves resulting from the reflection at the free surface might affect the recordings down to more than 100 m depth (see also Fig. 4.33 in Chapter 4). Yamada et al. (2010) estimated non-linear effects during strong shaking applying a deconvolution approach. Mogi et al., (2010) studied non-linear soil behaviour using a normalised input-output normalisation method. Parolai et al., (2010) showed that a robust estimate of an average  $Q_s$ , that can be used for numerical simulations of ground motion, can be obtained by means of deconvolution of array recordings. Figure 14.5 shows an example of borehole recordings and of the relevant deconvolved wavefield.

It is worth noting how the ground motion is modified (in general amplified) with decreasing depth of recording, being largest at the surface. For this surface amplification effect see also Fig. 4.22 in Chapter 4 and Table 1 in EX 3.4. The deconvolved wavefield, obtained by analysing the signal window indicated in red in the left panel, clearly shows a peak in the a-causal (negative times) part of the signal propagating toward the surface with a velocity consistent with the S-wave velocity in the borehole (red dashed line). A peak corresponding to a downgoing wave is observed also at all the depths analyzed in the causal (positive times) part of the signal. But the downgoing wave peak has always smaller amplitude than the upgoing one due to the effect of attenuation.

**Fig. 14.5 Left-hand panel:** horizontal component of ground acceleration recorded at different depths. Red record traces indicate the window containing S waves. **Right hand panel:** the upgoing (left) and downgoing (right) S waves in the deconvolved wavefield. The S-wave traveltimes, computed from the velocity model derived with the Parolai et al. (2005) inversion scheme, are indicated by the broken red lines.

## 14.3 Seismic noise measurements

### 14.3.1 Seismic Noise Horizontal-to-Vertical spectral ratio (NHV)

Nakamura (1989) revised the Horizontal-to-Vertical (H/V) seismic noise spectral ratio technique (NHV), first proposed by Nogoshi and Igarashi (1970 and 1971). Since then, in the field of site effect estimation, a large number of studies have been published, which use this

low cost, fast and therefore attractive technique (e.g. Field and Jacob, 1993; Lermo and Chavez-Garcia, 1994; Mucciarelli, 1998; Bard, 1999; Parolai et al., 2001b).

While in the Nakamura interpretation the NHV spectral ratio is directly related to the S-wave site response, most of the seismological/engineering community, based on the results of recent studies, is more inclined to consider predominant the role of surface waves (see e.g. Bard, 1999).

Most of the researchers focused their attention on the comparison of noise H/V spectral ratio and earthquake site response and agreed that the H/V spectral ratio of seismic noise provides a fair estimate of the fundamental resonance frequency of a site (Fig. 14.6). However, attempts to provide standards for the analysis of seismic noise have only recently been carried out (Bard, 1999; SESAME, 2003; Picozzi et al., 2005a). When using the NHV technique particular attention must be paid to the used seismic instruments and sensors (Guiller et al., 2007; Strollo et al., 2008a and b). Resonance frequency maps for large urban areas were recently provided by Parolai et al. (2001b) (Cologne, Germany), Duval et al. (2001) (Caracas, Venezuela), Picozzi et al. (2008) (Istanbul, Turkey), Bonnefoy-Claudet et al. (2009), Pilz et al. (2009 and 2010) (Santiago de Chile, Chile), Parolai et al. (2010b) (Bishkek, Kyrgyzstan, Figure 14.7), after validation with earthquake data.

**Fig. 14.6** Example of NHV ratio. The peak allows an estimate of the fundamental resonance frequency of the site (redrawn from Parolai and Galliana-Merino, 2006).

**Fig. 14.7** Fundamental resonance frequency map of Bishkek (Kyrgyzstan). The crosses indicate sites where single station noise measurements were carried out. The map was obtained after interpolation between these points. A geological legend and sketch of the area is also shown.

#### 14.3.1.1 Relationship between NHV peak frequency and thickness of the sedimentary cover

Recent studies (Yamanaka et al., 1994; Ibs-von Seht and Wohlenberg, 1999; Delgado et al., 2000 a and b; Parolai et al., 2002; D'Amico et al., 2008) showed that noise measurements can be used to map the thickness of soft sediments. Quantitative relationships between this thickness and the fundamental resonance frequency of the sedimentary cover as determined from the peak in the NHV spectral ratio were calculated for different basins in Europe (e.g. Ibs-von Seht and Wohlenberg, 1999; Delgado et al., 2000 a).

The approach is based on the assumption that in the investigated area, lateral variations of the S-wave velocity are minor and that it mainly increases with depth following a relation like

$$v_s(z) = v_{s0}(1 + Z)^x \quad (14.4)$$

where  $v_{s0}$  is the surface shear-wave velocity,  $Z = z/z_0$  (with  $z_0 = 1$  m) is the depth relative to  $z_0$  and  $x$  describes the depth dependence of velocity. Taking this into account and considering the well-known relation among  $f_r$  (the resonance frequency), the average S-wave velocity of soft sediments  $\bar{V}_s$ , and the layer thickness  $h$ ,

$$f_r = \bar{V}_s / 4h, \quad (14.5)$$

the dependency between thickness and  $f_r$  can be written as

$$h = \left[ v_{s0} \frac{(1-x)}{4f_r} + 1 \right]^{1/(1-x)} \quad (14.6)$$

where  $f_r$  is to be given in Hz,  $v_{s0}$  in m/s and  $h$  in m. Moreover, empirical relationships between  $f_r$  and  $h$  in the form

$$h = a f_r^b \quad (14.7)$$

can also be derived, generally applying grid search procedures.

The above approximate interpretation can be easily extended to the case of a two layer sedimentary cover (D'Amico et al., 2008). Despite the fact that relatively large errors affect the depth estimates provided by this approach (D'Amico et al., 2004) it can be considered as a useful proxy for more costly exploratory surveys.

#### 14.3.1.2 NHV inversion

Recently, the possibility of retrieving the S-wave velocity structure below a site from single station measurements based on NHV ratio computation was tested by Fäh et al. (2001). They suggested a new method for calculating NHV ratios employing a frequency-time analysis (FTAN). Moreover, after having shown that there is a good agreement between the NHV ratio and the theoretical ellipticity curves of the fundamental mode Rayleigh wave, they proposed to invert the NHV curve to derive directly the S-wave subsoil structure. The NHV was corrected for the contamination by SH and Love waves by simply reducing it by a factor  $\sqrt{2}$ , independent of frequency, under the assumption of an equal contribution to the seismic noise wavefield of Love and Rayleigh waves. The inversion, due to the non-linear nature of the problem, was based on a genetic algorithm (GA) (Fäh et al., 2001, 2003). The inversion is carried out for a fixed number of layers and a-priori defined ranges of the geophysical properties (S- and P-wave velocity, density and thickness) of the layers. An initial starting population of individuals is generated through a uniform distribution in the parameter space. The model that, amongst all those generated, allows the best reproduction of the observed NHV, is chosen as the best model.

Parolai et al. (2006) adopted this technique to derive S-wave velocity profiles in the Cologne area. Their inversions were carried out by fixing the total thickness of the sedimentary cover in order to avoid problems of trade-off between the total thickness and the S-wave velocity (Scherbaum et al., 2003; Arai and Tokimatsu, 2004). For each site, different inversions were carried out, varying the thickness of the sedimentary layer considering the uncertainty in its estimate. The best models obtained from each inversion were averaged.

In Parolai et al. (2006) the inversion of NHV curves was extended to 20 of the sites measured by Parolai et al. (2001b) and a 2-D S-wave velocity model was derived by means of interpolating between the derived 20 depth profiles. Figure 14.8 shows the resulting 2-D S-wave velocity model (bottom) together with the geological cross-section. The agreement between the geological structure obtained by interpretation of boreholes data and surface geology, and the S-wave velocity model is very good. Compared to the average velocity relationship previously derived for the whole area (Parolai et al., 2002; see also section 14.3.1.1), lateral variations in the velocity structure are clearly visible.

**Fig. 14.8** Top: Geological cross section of the sedimentary cover in Cologne (redrawn after Von Kamp, 1986) y = Landfills, q = Quaternary, pl = Pliocene, mi = Miocene, ol = Oligocene, dv = Devonian. Bottom: 2-D S-wave velocity model interpolated from 1-D S-wave velocity profiles calculated for 20 selected sites where the NHV was inverted. The striped pattern indicates the Devonian bedrock inverted (modified after Parolai et al., 2006).

Therefore, in this case of well constrained bedrock depth, it could be shown that the sedimentary cover is fairly regularly layered, and the NHV inversion a suitable method for quickly mapping 3-D S-wave velocity structures. The vertical resolution of the profiles was also found sufficient to provide site responses (Parolai et al., 2006; Parolai et al., 2007) by means of numerical simulations, in agreement with the empirical ones.

Recently, improvement in the forward calculation of NHV spectral ratios were proposed by Arai and Tokimatsu (2000, 2004) and applied in a joint inversion scheme of NHV and dispersion curves by Parolai et al. (2005), Picozzi and Albarello (2007) and D'Amico et al. (2008).

Arai and Tokimatsu (2000) showed that NHV spectral ratios can be better reproduced if the contribution of higher modes of Rayleigh waves and Love waves is also taken into account. They suggest to calculate the NHV spectral ratio as

$$(\text{NHV})_s = (P_{\text{HS}}/P_{\text{VS}})^{1/2} \quad (14.8)$$

where the sub-index  $s$  stands for surface waves, and  $P_{\text{VS}}$  and  $P_{\text{HS}}$  are the vertical and horizontal powers of surface waves (Rayleigh and Love), respectively.

The vertical power of the surface waves is only determined by the vertical power of Rayleigh waves ( $P_{\text{VR}}$ ), while the horizontal power involves the contribution of both Rayleigh ( $P_{\text{HR}}$ ) and Love waves ( $P_{\text{HL}}$ ). The following equations can therefore be used (Harkrider, 1964):

$$P_{\text{VS}} = P_{\text{VR}} = \sum_j (A_{\text{Rj}}/k_{\text{Rj}})^2 \left\{ 1 + (\alpha^2/2)(u/w)_j^2 \right\} \quad (14.9)$$

$$P_{\text{HS}} = P_{\text{HR}} + P_{\text{HL}} \quad (14.10)$$

$$P_{\text{HR}} = \sum_j (A_{\text{Rj}}/k_{\text{Rj}})^2 (u/w)_j^2 \left\{ 1 + (\alpha^2/2)(u/w)_j^2 \right\} \quad (14.11)$$

$$P_{\text{HL}} = \sum_j (A_{\text{Lj}}/k_{\text{Lj}})^2 (\alpha^2/2) \quad (14.12)$$

where  $A$  is the medium response,  $k$  is the wavenumber,  $u/w$  is the H/V ratio of the Rayleigh mode at the free surface,  $j$  is the mode index, and  $\alpha$  is the H/V ratio of the loading horizontal and vertical forces  $L_{\text{H}}/L_{\text{V}}$ .

Picozzi et al. (2005b) showed that varying  $\alpha$  over a large range did not significantly changed the NHV shape. Therefore, they used  $\alpha=1$ .

A basic problem of these inversion procedures concerns the choice of the frequency band to be used for the inversion of the NHV curve. As an example, the NHV values around the maximum have been discarded by Parolai et al. (2006) since the effect of smoothing of the spectra biases the amplitude estimation around this frequency band. Instead, they have been taken into account by Picozzi and Albarello (2007) and D'Amico et al., (2008), who tried to exploit the effect of higher modes around the fundamental resonance frequency value. Recent theoretical studies (Lunedei and Albarello, 2009; Albarello and Lunedei, 2009) indicate that the NHV curve around the fundamental resonance frequency  $f_0$  (i.e., around the NHV maximum) can be significantly affected by the damping profile in the subsoil and by the distribution of sources around the receiver. In particular, they showed that sources located within few hundreds of meters from the receiver can generate seismic phases that strongly affect the shape of the NHV curve around and below  $f_0$ . This implies that, unless a large source-free area exists around the receiver, inversion of the NHV shape (around and below  $f_0$ ) carried out by using forward models based on surface waves only, might provide biased results. However, these conclusions still need to be confirmed by comparison with real data.

Recently, Pilz et al. (2010) obtained a 3-D S-wave velocity model of the Santiago de Chile basin by inverting with this method the NHV ratio calculated in Pilz et al. (2009). In order to reduce the trade-off between thickness of the sedimentary cover and S-wave velocity they constrained the former to values derived by previously carried out gravimetric measurements. An example of the results is shown in Figure 14.9.

**Figure 14.9** **Left:** Example of S-wave velocity profile derived by NHV inversion. The best model (white line), the models lying within the 10% of the minimum misfit (black lines) and all the tested models (gray lines) are shown. The bottom panel shows the observed (gray circles) and calculated (empty circles) for the best models NHV. **Right:** The 3-D model of the Santiago de Chile basin obtained by interpolating between the S-wave velocity-depth profiles like the one in the upper left corner of this figure. The color scale indicates the S-wave velocities in m/sec.

## 14.4 2-D arrays

Seismic arrays were originally proposed at the beginning of the 1960s as a new type of seismological tool for the detection and identification of nuclear explosion (e.g., Bormann, 1966; Frosch and Green, 1966). Since then, seismic arrays have been applied at various scales for many geophysical purposes. At the seismological scale, they were used to obtain refined velocity models of the Earth's interior (e.g., Birtill and Whiteway, 1965; Whiteway, 1966; Kværna, 1989; Káráson and van der Hilst, 2001; Ritter et al., 2001; Krüger et al., 2001). Reviews on array applications in seismology can be found in Chapter 9 of this Manual, in Douglas (2002) and in Rost and Thomas (2002). At smaller scales, since the pioneering work of Aki (1957), seismic arrays have been used for the characterization of surface wave

propagation, and the extraction of information on the shallow subsoil structure (i.e., the estimation of the local S-wave velocity profile). Especially in the last decades, due to the focus of seismologists and engineers on estimating the amplification of earthquake ground motion as a function of local geology, the improvements in the quality of instrumentation and computing power, interest in analyzing seismic noise recorded by arrays has grown (e.g., Horike, 1985; Hough et al., 1992; Ohori et al., 2002; Okada, 2003; Scherbaum et al. 2003; Parolai et al., 2005; Tada et al., 2006; Asten, 2006; Köhler et al., 2007). A review on array application for site classification can be found in Foti et al. (2011).

### 14.4.1 f-k based methods

The phase velocity of the surface waves can be extracted from noise recordings by using different methods. Here we will illustrate the two most frequently used methods for f-k (frequency-wavenumber) analysis: the Beam-Forming Method (BFM) (Lacoss et al., 1969) and the Maximum Likelihood Method (MLM) (Capon, 1969).

The estimate of the f-k spectra  $P_b(f, k)$  by the BFM is given by:

$$P_b(f, k) = \sum_{l,m=1}^n \phi_{lm} \exp\{ik(X_l - X_m)\} , \quad (14.13)$$

where  $f$  is the frequency,  $k$  the two-dimensional horizontal wavenumber vector,  $n$  the number of sensors,  $\phi_{lm}$  the estimate of the cross-power spectra between the  $l^{\text{th}}$  and the  $m^{\text{th}}$  recordings, and  $X_l$  and  $X_m$ , are the coordinates of the  $l^{\text{th}}$  and  $m^{\text{th}}$  sensors, respectively.

The MLM gives the estimate of the f-k spectra  $P_m(f, k)$  as:

$$P_m(f, k) = \left( \sum_{l,m=1}^n \phi_{lm}^{-1} \exp\{ik(X_l - X_m)\} \right)^{-1} . \quad (14.14)$$

Capon (1969) showed that the resolving power of the MLM is higher than that of the BFM, however, the MLM is more sensitive to measurement errors.

From the peak in the f-k spectrum occurring at coordinates  $k_{xo}$  and  $k_{yo}$  for a certain frequency  $f_0$ , the phase velocity  $c_0$  can be calculated by:

$$c_0 = \frac{2\pi f_0}{\sqrt{k_{xo}^2 + k_{yo}^2}} . \quad (14.15)$$

An extensive description of these methods can be found in Horike (1985) and Okada (2003).

The estimate  $EP_b$  and  $EP_m$  of the true  $P_b$  and  $P_m$  f-k spectra may be considered in the convolution of the true functions with a frequency window function  $W_f$  and the wavenumber window functions  $W_B$  and  $W_M$  for the BFM and MLM, respectively (Lacoss *et al.*, 1969). The first window function  $W_f$  is the transfer function of the tapering function applied to the signal time windows (Kind, 2005). The function  $W_B$  is termed differently by various authors (e.g., “*spatial window function*” by Lacoss et al., 1969, and “*beam-forming array response function*” by Capon, 1969), and hereafter simply defined as Array Response Function (ARF). The ARF depends only on the distribution of stations in the array and has for the wavenumber vector  $k_o$  the form (Horike, 1985)

$$W_B(k, k_o) = \frac{1}{n^2} \sum_{l,m=1}^n \exp\{i(k - k_o)(X_l - X_m)\}. \quad (14.16)$$

Simply speaking, it represents a kind of spatial filter for the wavefield. The main advantage of the MLM with respect to the BFM involves the use of an improved wavenumber window  $W_M$ . Namely, for a wavenumber  $k_o$  this window function may be expressed in the form

$$W_M(f, k, k_o) = \left| \sum_{j=1}^N A_j(f, k_o) \right| W_B(k, k_o), \quad (14.17)$$

where

$$A_j(f, k_o) = \frac{\sum_{l=1}^N q_{jl}(f, k_o)}{\sum_{j,l=1}^N q_{jl}(f, k_o)} \quad (14.18)$$

and  $q_{jl}$  represents the elements of the cross-power spectral matrix. It is evident that  $W_M$  depends not only on the array configuration, through the function  $W_B$ , but also on the quality (i.e., signal-to-noise ratio) of the data (Horike, 1985). In fact, the wavenumber response is modified by using the weights  $A_j(f, k_o)$ , which depend directly on the elements  $q_{jl}(f)$ . In practice,  $W_M$  allows the monochromatic plane wave travelling at a velocity corresponding to the wavenumber  $k_o$  to pass undistorted, while it suppresses, in an optimum least-square sense, the power of those waves travelling with velocities corresponding to wavenumbers other than  $k_o$  (Capon, 1969). Or, in other words, coherent signals are associated with large weights of  $A_j$  and their energy is emphasized in the f-k spectrum. On the contrary, if the coherency is low, the weights  $A_j$  are small and the energy in the f-k spectrum is damped (Kind et al., 2005). This automatic change of the main-lobe and side-lobe structure minimizes the leakage of power from the remote portion of the spectrum and has a direct positive effect on the  $P_m$  function, and consequently on the following velocity analysis. However, considering the dependence of  $W_M$  on  $W_B$ , it is clear that the array geometry is a factor which has a strong influence on both  $EP_b$  and  $EP_m$ . In fact, similarly to every kind of filter, several large side lobes located around the major central peak can remain in the f-k spectra (Okada, 2003) and cause serious biases in the velocity and back-azimuth estimates. In particular, side-lobe height and main-lobe width within  $W_B$  control the leakage of energy and resolution, respectively (Zywicki, 1999).

As a general criterion, the error in the velocity analysis due to the presence of spurious peaks in the f-k spectra may be reduced using distributions of sensors for which the array response approaches a two-dimensional  $\delta$ -function. For that reason, it is considered a good practice to undertake a preliminary evaluation of the array response when the survey is planned. Irregular configurations of even only a few sensors should be preferred, because they allow one to obtain a good compromise between a large aperture, which is necessary for sharp main peaks in the  $EP_b$  and  $EP_m$ , and small inter-sensor distances, which are needed for large aliasing periods (Kind et al., 2005).

Recently, Picozzi et al. (2010a) showed that removing the effect of the array response from the frequency wavenumber images by using the Richards-Lucy regularization method improve the phase velocity estimation.

Fig.14.10 shows an example of 2-D-array configuration and its respective array responses. Figure 14.11 shows an example of f-k analysis results for 3.15 Hz, 5.6 Hz, and 9.9 Hz for the array configuration of Fig. 14.10. White dots indicate the position of the maximum used to estimate the phase velocity while the white circles join points with the same k values.

**Fig. 14.10 Top:** Example of a micro-array configuration. The blue triangles indicate the station positions. **Bottom:** The relevant micro-array response estimated for the frequency of 15 Hz.

**Fig. 14.11** Example of results from f-k analysis for 3.15 Hz, 5.6 Hz, and 9.9 Hz. White dots indicate the position of the maximum used to estimate the phase velocity. The circles join points with the same  $k$ . In this case at frequencies of 5.6 and 9.9 Hz the velocity of propagation of waves can be estimated and the source position identified (red color in the maps). (Comment: There are as many white dots as circles. Thus both has to be plural)

#### 14.4.2 Spatial and Extended Spatial Autocorrelation method (SPAC and ESAC )

Aki (1957 and 1965) showed that phase velocities in sedimentary layers can be determined using a statistical analysis of ambient noise. He assumed that noise represents the sum of plane waves propagating without attenuation in a horizontal plane in different directions with different powers, but with the same phase velocity for a given frequency. He also assumed that waves with different propagation directions and different frequencies are statistically independent. Then, a spatial correlation function can be defined as

$$\phi(r, \lambda) = \langle u(x, y, t)(x + r \cos(\lambda), y + r \sin(\lambda), t) \rangle \quad (14.19)$$

where  $u(x, y, t)$  is the velocity observed at point  $(x, y)$  at time  $t$ ;  $r$  is the inter-station distance;  $\lambda$  is the azimuth and  $\langle \rangle$  denotes the ensemble average. An azimuthal average of this function is given by

$$\phi(r) = \frac{1}{\pi} \int_0^\pi \phi(r, \lambda) d\lambda. \quad (14.20)$$

For the vertical component, the power spectrum  $\phi(\omega)$  can be related to  $\phi(r)$  via the zero<sup>th</sup> order Hankel transform:

$$\phi(r) = \frac{1}{\pi} \int_0^{\infty} \phi(\omega) J_0\left(\frac{\omega}{c(\omega)} r\right) d\omega, \quad (14.21)$$

where  $\omega$  is the angular frequency,  $c(\omega)$  is the frequency-dependent phase velocity, and  $J_0$  is the zero order Bessel function. The space-correlation function for one angular frequency  $\omega_0$ , normalized to the power spectrum, will be of the form

$$\phi(r, \omega_0) = J_0\left(\frac{\omega_0}{c(\omega_0)} r\right). \quad (14.22)$$

By fitting the azimuthally averaged spatial correlation function obtained from measured data to the Bessel function, the phase velocity  $c(\omega_0)$  can be calculated. A fixed value of  $r$  is used in the spatial autocorrelation method (SPAC). However, Okada (2003) and Ohori et al. (2002) showed that, since  $c(\omega)$  is a function of frequency, better results are achieved by fitting the spatial-correlation function at each frequency to a Bessel function, which depends on the inter-station distances (extended spatial autocorrelation, ESAC). For every couple of stations the function  $\phi(\omega)$  can be calculated in the frequency domain by means of (Malagnini et al., 1993; Ohori et al., 2002; Okada, 2003):

$$\phi(\omega) = \frac{\frac{1}{M} \sum_{m=1}^M \text{Re}( {}_m S_{jn}(\omega) )}{\sqrt{\frac{1}{M} \sum_{m=1}^M {}_m S_{jj}(\omega) \sum_{m=1}^M {}_m S_{nn}(\omega)}}, \quad (14.23)$$

where  ${}_m S_{jn}$  is the cross-spectrum for the  $m$ th segment of data, between the  $j^{\text{th}}$  and the  $n^{\text{th}}$  station;  $M$  is the total number of used segments. The power spectra of the  $m^{\text{th}}$  segments at station  $j$  and station  $n$  are  ${}_m S_{jj}$  and  ${}_m S_{nn}$ , respectively.

The space-correlation values for every frequency are plotted as a function of distance, and an iterative grid-search procedure can then be performed using equation (14.22) in order to find the value of  $c(\omega_0)$  that gives the best fit to the data. The tentative phase velocity  $c(\omega_0)$  is generally varied over large intervals (e.g., between 100 and 3000 m/s) in small steps (e.g., 1 m/s). The best fit is achieved by minimizing the root mean square (RMS) of the differences between the values calculated with equation (14.21) and (14.22). Data points, differing more than two standard deviations from the value obtained with the minimum-misfit velocity, can be removed before the next iteration of the grid-search. Parolai et al. (2006) used this procedure and allowed for a maximum of three grid-search iterations. An example of the application of this procedure is shown Fig. 14.12.

Several studies, (e.g. Parolai et al., 2009, Foti et al., 2011) showed the reliability of the procedure in deriving a robust estimate of the dispersion curve that lead to S-wave velocity profiles consistent with those obtained by other geophysical methods.

**Fig. 14.12 Top:** Measured space-correlation function values for different frequencies (black and blue circles) and the best-fitting Bessel function (gray circles). Discarded values (blue circles) lie two standard deviations outside the curve. **Bottom:** The respective RMS error versus phase velocity curves.

The ESAC method can be adopted to derive the phase velocities for all frequencies composing the Fourier spectrum of the data. Figure 14.12 shows on top three examples of the space-correlation values computed from the data together with the best fitting Bessel functions and below the corresponding RMS errors as function of the tested phase velocities, exhibiting clear minima. For high frequencies, the absolute minimum might sometimes corresponds to the minimum velocity chosen for the grid search procedure. This solution is then discarded, because a smooth variation of the velocity between close frequencies is required. At frequencies higher than a certain threshold the phase velocity might increase linearly. This effect is due to spatial aliasing which limits the upper bound of the usable frequency band. It depends on the S-wave velocity structure at the site and the minimum inter-station distance. At low frequencies the RMS error function clearly indicates the lower boundary for acceptable phase velocities, but might not be able to constrain the higher ones (then a plateau can appear in the RMS curves). The frequency above which phase differences cannot be resolved any more depends on the maximum inter-station distance and the S-wave velocity structure below the site: a wide range of velocities will then explain the observed small phase differences. Zhang et al. (2004) clearly pointed out this problem in Equation (3a) of their article.

Figure 14.13 gives an example of the final dispersion curve. The typical behaviour of f-k methods, namely of BFM to yield higher phase velocities than the ESAC method at low frequencies (Okada 2003), is clearly to be seen. Yet, Okada (2003) showed that by increasing the array size, the f-k velocities at low frequencies become similar to those estimated by ESAC, indicating that the latter is more suitable for providing reliable dispersion curves over

a wider frequency range, especially toward lower frequencies (and thus with greater penetration depths).

**Fig. 14.13** Phase velocity dispersion curves obtained by ESAC (reds line), BFM (green line) and MLM (blue line) analysis. The dotted line indicate the theoretical aliasing limit calculated as  $4 f_{dmin}$ , where  $d_{min}$  is the minimum interstation distance. The factor 4 is used instead of the generally used factor 2, because the minimum distance in the array is appearing only once. The dashed gray line indicates the lower frequency threshold of the analysis based on  $2\pi f \Delta k$  where  $\Delta k$  is calculated as the half-width of the main peak in the array response function. The continuous line indicates the lower frequency threshold of the analysis based on the equation  $3 f_{dmax}$ , where  $d_{max}$  is the maximum interstation distance in the array

Figure 14.14 summarises the procedure used with the ESAC and f-k methods.

**Fig. 14.14** Summary of the procedure used with the ESAC and *f-k* methods (from Picozzi, 2006)

## 14.5 Interferometry and tomography

Recent theoretical studies have shown that the cross-correlation of diffuse wavefields can provide an estimate of the Green's functions between receivers (Weaver and Lobkis, 2001 and 2004; Snieder, 2004; Wapenaar, 2004; Wapenaar and Fokkema, 2006). Using coda waves of seismic events (Campillo and Paul, 2003) and long seismic noise sequences (Shapiro and Campillo, 2004), it was confirmed that it is possible to estimate the Rayleigh wave component of Green's functions between two stations by the cross-correlation of simultaneous recordings. This method is now generally referred to as seismic interferometry. These results allowed the first attempts of surface wave tomography at regional scales (e.g., Shapiro and Campillo, 2004; Sabra et al., 2005; Shapiro et al., 2005; Gerstoft et al., 2006; Yao et al., 2006; Cho et al., 2007; Lin et al., 2007; Yang et al., 2007) using seismic noise recordings from broad-band seismic networks. Generally, for these kinds of studies, waves at frequencies well below 1 Hz were used to image the crust and the upper-mantle structure. A comprehensive review of the seismic interferometry method can be found in Curtis et al. (2006).

Seismic noise interferometry can also be applied to frequencies larger than 1Hz. Schuster (2001) and Schuster et al. (2004) demonstrated the possibility of forming an image of the subsurface using the cross-correlation of seismic responses from natural and man-made sources at the surface or in the subsurface. Furthermore, within the context of exploration geophysics, Bakulin and Calvert (2004 and 2006) first proposed a practical application of seismic interferometry, showing that it is possible in practice to create a virtual source at a subsurface receiver location in a well. Other recent applications for the high-frequency range have been proposed by Dong and Schuster (2006) and Halliday et al. (2007) for surface-wave isolation and removal in active-source surveys. Among the several reasons that have stimulated the application of seismic noise interferometry to high frequencies, one is the possibility of applying this technique to suburban settings (Halliday et al., 2008), and another to exploit it for engineering seismology purposes, which require knowledge of the subsurface structure from depths of a few meters to several hundred meters.

The application of seismic noise interferometry to high frequencies is not merely a change of scale, since it involves also important questions still under discussion within the research community. For example, the effects of the high spatial and temporal variability in the distribution of noise sources occurring at high frequencies are still under investigation (Halliday and Curtis, 2008a and b), as well as the relationship between the wavelength of interest and inter-station distances. Several authors (e.g., Chavez-Garcia and Luzon, 2005; Chavez-Garcia and Rodriguez, 2007; Yokoi and Margaryan, 2008) showed, for a small scale experiment at a site with a homogeneous subsoil structure, the equivalence between the results obtained by cross-correlation in the time domain and the SPatial Auto-Correlation analysis (SPAC) method (Aki, 1957). However, it is worth noting that for non-homogeneous subsoil conditions, the SPAC method suffers a severe drawback. Indeed, as a general rule, such a method is used to retrieve the shallow soil structure below a small array of sensors by means of inversion of surface wave dispersion curves extracted by seismic noise analysis. Yet, the inversion is performed under the assumption that the structure below the site is nearly 1-D. Therefore, if the situation is more complicated (2-D or 3-D structure), then the SPAC method can only provide a biased estimate of the S-wave velocity structure. In contrast, one can expect that, similarly to what is obtained over regional scales, local heterogeneities will affect the noise propagation between sensors, and hence can be retrieved by analysing the Green's function estimated by the cross-correlation of the signals recorded at two different stations. For this reason, passive seismic interferometry is also believed to be a valuable tool for studying complex structures and performing surface wave tomography also for smaller

spatial scales of investigation. Picozzi et al. (2008) verified the suitability of seismic interferometry for seismic engineering and microzonation purposes. In fact, after having first evaluated the possibility of retrieving reliable and stable Green's functions within the limitations of time and instrumentation that bound standard engineering seismological experiments (for example, in urban microzonation studies, the number of deployed sensors is generally not larger than 20 and the acquisition time does not last more than a few hours), they applied the seismic interferometry technique to recordings from a 21-station array installed in the Nauen test site (Germany) (Yaramanci et al., 2002; and [http://www.geophysik.tu-berlin.de/menue/forschung/testfeld\\_nauen/uebersicht](http://www.geophysik.tu-berlin.de/menue/forschung/testfeld_nauen/uebersicht)). They showed that passive seismic interferometry is a valuable tool for the characterization of near-surface geology since the travel times estimated from the Green's functions analysis for different frequencies were inverted to derive the laterally varying 3-D surface wave velocity structure below the array, and with a few further steps the S-wave velocity structure as well. This represents a major innovation, due to the frequency range investigated and the scale of the experiment,

Figure 14.15 shows a 2-D cross section highlighting lateral velocity variations as inferred by seismic tomography from the application of seismic interferometry to seismic noise (Picozzi et al., 2008).

**Fig. 14.15:** S-wave velocity section extending southwest to northeast in the centre of the study area of Picozzi et al. (2008), derived by seismic noise tomography.

Furthermore, recent technical development (Picozzi et al., 2010b), show that in future it will be possible to overcome the problem of the high costs associated with of the application of this technique, caused by the large number of instruments required by using ad-hoc developed low-cost sensors.

## 14.6 Conclusions, suggestions and related case studies

Estimating site effects in large urban areas is a challenging task for seismologists and engineers. On the one hand, detailed site investigations are necessary for optimal design of buildings and foundations, while on the other hand urban planning and seismic risk mitigation actions could rely also on more general information about site amplification. Furthermore, the area that should be covered by related investigations for megacities might require large

investments and a long duration of the experiments. The rapid growth and expansion of populated areas, especially in developing countries, might even render the studies already outdated soon after their completion. A reasonable compromise between collection of empirical data at acceptable cost and within realistic time-frames can only be based on a mixed approach that combines the acquisition of high-quality (and thus high-cost) information at few sites with the application of rapid low-cost methods that allow for an extrapolation of the information over wide areas. With this aim, seismic microzonation of large urban areas can be carried out on the basis of site effect studies, which should involve:

- 1) Collection of all already available geological, geotechnical, and geophysical data.
- 2) Installation of a temporary seismic network for recording of earthquake data (about 3 months in duration). Local, regional and teleseismic events provide the necessary inputs for site effect estimation. The different frequency content of the recordings allows to cover the whole frequency range of engineering interest. The stations should be installed at characteristic sites taking into account the surface geology, topography and the expected depth variations of the bedrock surface.
- 3) Seismic noise recordings at single stations. Measurements should be carried out for at least 30 minutes at each site following the recommendation of SESAME (2003) ([http://sesame-fp5.obs.ujf-grenoble.fr/SES\\_Home\\_Description.htm](http://sesame-fp5.obs.ujf-grenoble.fr/SES_Home_Description.htm)) and Picozzi et al. (2005a). In particular attention should be paid to the instruments used (Guiller et al., 2007; Strollo et al., 2008a and b). After calibration through comparison with earthquake data the fundamental resonance frequency estimated by NHV can be used for preparing maps. If an estimation of the thickness of the sedimentary layers is available, NHV can be inverted to derive S-wave velocity profiles. These, in turn, can be used to calculate 1-D site response or to generate 2-D and 3-D models that provide a basis for computing ground motion scenarios.
- 4) S-wave velocity profiles can be estimated using seismic noise arrays. .

Although these noise-based methods cannot be considered in general a substitute of investigation techniques dealing with active sources (that might provide more detailed information about the subsoil structure) they have the advantage to be easily applicable in urban areas (where method based on active sources might be impossible or suffer problems) and allow for investigating the subsurface structure down to large depths in a cost-effective way.

Tables 14.1 and 14.2 summarize essential points to be considered in the acquisition and analysis of earthquake data and seismic noise data, respectively, when carrying out such investigations. In the case that non-linear soil behaviour is likely this should be investigated by drilling of shallow boreholes and collection of undisturbed samples at a limited number of representative sites. If available funding allows for long-term monitoring, and improvement of estimates of site response for different levels of ground motion, the installation of vertical array of accelerometers should be considered. A similar combined approach was recently followed for different large urban areas. Parolai et al. (2004) installed a network of 40 seismological stations in the urban area of Cologne (Germany). Moreover they performed single station noise analysis at nearly 400 sites (Parolai et al., 2001b) and estimated the S-wave velocity at two sites by means of seismic noise array data analysis (Parolai et al. 2005; Parolai et al. 2006).

Parolai et al. (2010b) installed a network of 20 seismological stations in Bishkek and carried out single station noise measurements at nearly 200 sites (Figure 15.7).

**Table 14.1 Suggestions for collection and analysis of earthquake data**

|                                                                   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Acquisition</b>                                                | <ul style="list-style-type: none"> <li>- A sample rate of at least 100 s.p.s is suggested</li> <li>- Continuous recording allows to collect seismic noise and to record also regional and teleseismic events that might be masked by high frequency noise</li> <li>- Short period sensors might provide a reasonable compromise between the data quality and the temporary (low quality generally) installation.</li> </ul>                                                                                                                                                                                                                                                                                                                                    |
| <b>Data analysis: window selection</b>                            | <p>The window length can be selected following different criteria:</p> <ul style="list-style-type: none"> <li>- fixed window lengths (be careful that all the significant part of ground motion is included);</li> <li>- window length selected on the base of energy criteria, e.g., including only part of signal containing 80% or 90% of the energy.</li> </ul> <p>Remember that frequency resolution is related to the total window length used.</p> <p>Since generally windows are tapered at both ends before the Fourier transform, the starting of the window should be selected in order to avoid that tapering is affecting the signal of interest. If, for example S waves are of interest, the window should start before the S-wave arrival.</p> |
| <b>Data analysis: Baseline correction, Tapering and smoothing</b> | <p>Removing the average of the signal might be necessary before calculating the Fast Fourier transform (FFT).</p> <p>Tapering at both ends is generally performed using windows. The percentage of tapering can vary. A generally used value is 5% of the signal length.</p> <p>The FFT of the signal should be smoothed, in order to avoid numerical instabilities. However, smoothing should allow to preserve the main features in the spectra. When spectra are spanning more than one decade it is preferable to smooth them using relative bandwidth windows.</p>                                                                                                                                                                                        |

**Table 14.2 Suggestions for collection and analysis seismic noise data**

|                                                                                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Acquisition</b>                                                                             | <ul style="list-style-type: none"> <li>- A sample rate of at least 100 s.p.s is recommended for single station noise measurements. Depending on the minimum inter-station distance, in the case of arrays, even larger sampling rates are suggested.</li> <li>- Short-period sensors might provide a reasonable compromise between high data quality and temporary installations of generally low data quality.</li> <li>- Please, check if the level of seismic noise is higher than the internal noise of the sensor+acquisition system in the frequency range of interest (see Chapter 5, section 5.5.6).</li> </ul>                                                                        |
| <b>Data analysis: window selection</b>                                                         | <p>The windows should be selected keeping in mind the frequency band of interest. The maximum usable frequency is limited by the Nyquist frequency due to the sampling rate. The minimum frequency that can be analyzed is determined by the length of the selected signal window. However, stable results are expected only for frequencies that have a reasonable number of cycles (at least 10) within the selected signal window.</p> <p>In the case that the frequency range of interest spans between 0.1 and 10 Hz, window lengths of 20-60 seconds are suggested.</p>                                                                                                                  |
| <b>Data analysis: Baseline correction, tapering, smoothing and number of analysed windows.</b> | <p>Removing the average of the signal might be necessary before calculating the FFT.</p> <p>Tapering at both ends is generally performed using windows. The percentage of tapering can vary. A generally used value is 5% of the signal length.</p> <p>The FFT of the signal should be smoothed, in order to avoid numerical instabilities. However, smoothing should allow to preserve the main features in the spectra. When spectra are spanning more than one decade it is preferable to smooth them using relative bandwidth windows.</p> <p>When the frequency range of interest is 0.1-10 Hz at least 20 minutes of noise (divided in windows of 20-60 seconds) should be analysed.</p> |

Similarly, Picozzi et al. (2009), estimated the fundamental resonance frequency in western Istanbul (Turkey) by means of nearly 200 single station noise measurements. The reliability of the results was assessed by comparison with results from earthquake data obtained by analysing the recordings of the Istanbul Earthquake Rapid Response System (IERRS) operated by the Kandilli Observatory and Earthquake Research Institute of Bogazici University. Furthermore, eight 2-D array measurements of seismic noise were performed in the metropolitan area with the aim of obtaining a preliminary geophysical characterization of the different sedimentary covers. Comparison of the theoretical site response from an estimated S-wave velocity profile with the empirical one derived using earthquake recordings confirmed the suitability of the use of the low-cost seismic noise techniques for the study of seismic site effects.

Pilz et al. (2009) installed a temporary seismic network in Santiago de Chile (~6 million inhabitants). They estimate site amplification using the standard spectral ratio (SSR) method and proposed a map of the fundamental resonance frequency by analysing ~150 single station seismic noise recordings. Furthermore, by taking advantage of the available knowledge on bedrock depth from gravimetric measurements they derived a 3-D model of the basin that can be used for calculating realistic ground motion scenarios.

All these studies showed that the approach described above is feasible for covering large urban areas. at reasonable costs. Open questions still remain with respect to the estimation of a first order classification of soil that can be used, with a sufficient degree of reliability, at regional or even global scales.

## Acknowledgment

I am grateful to Dino Bindi, Matteo Picozzi, Marco Pilz and Tobias Boxberger for suggestions and comments that helped in improving this manuscript. Their help in drawing figures was also strongly appreciated. The manuscript also benefitted from valuable comments and suggestions by Peter Bormann, Adrien Oth and Pierre-Yves Bard.

As described in Chapter 14, a largely used method of seismic data analysis, which is often applied to study geophysical processes, consists in the spectral analysis of seismic signals after having carried out a Fourier transform of the time series.

However, for the analysis of noise data the recordings of some tens of minutes are usually subdivided into much shorter time windows (usually 30 s or 60 s). For earthquake recordings the spectral estimation of specific phases within a seismogram, particular those recorded at local and regional distances, can be difficult due to the difficulties in isolating a particular phase. On the contrary, mathematical principles require infinite long time series for performing a Fourier transform and, hence, such windowing will cause the Fourier transform to develop non-zero values predominantly at lower frequencies (commonly called spectral leakage, i.e. some frequencies tend to leak to other frequencies).

Therefore, it is standard practice to multiply the data windows by a taper before performing a Fourier transform. The taper consist in a function smoothly decaying to zero near the ends of each window, aimed at minimizing the effect of the discontinuity between the beginning and end of the time series. Although spectral leakage cannot be prevented it can be significantly reduced by changing the shape of the taper function in a way to minimize strong discontinuities close to the window edges.

Different types of tapers are shown in Figure 1. In seismic data analysis cosine tapers are often used, being both effective and easy to calculate, though bell-shaped and triangle functions are sometimes applied, too. In a mathematical form, the cosine taper can be written as

$$c(t) = \begin{cases} \frac{1}{2} \left( 1 - \cos \frac{\pi}{a} t \right) & \text{for } 0 \leq t \leq a \\ 1 & \text{for } a \leq t \leq (1-a) \\ \frac{1}{2} \left( 1 - \cos \frac{\pi}{a} (1-t) \right) & \text{for } (1-a) \leq t \leq 1 \end{cases}$$

with time  $t$  and taper ratio  $a$ . The cosine window represents an attempt to smoothly set the data to zero at the boundaries while not significantly reducing the level of the windowed transform.

Such tapering will lead to the following effects: It reduces the leakage of spectral power from a spectral peak to frequencies far away and it coarsens the spectral resolution by a factor  $1 / (1 - a)$  for the above cosine tapers.

**Figure 1** Comparison between the Dirichlet sharp-edged rectangle window function with two common taper functions.

The result of applying the cosine taper family of windows with a length of 30 s is presented in Figure 2. As the taper ratio  $a$  is decreased, or equivalently, as the shape of the window becomes increasingly rectangular, the bandwidth of the Fourier transform decreases. Therefore, a decreased taper ratio will increase the amount of leakage. As can be seen in Figure 2 (a), spectra from the untapered time series show a significant overestimation in spectral energy for low frequencies (leakage), resulting in a much lower H/V amplitude. Below 0.5 Hz the spectra for all three components show the same level of amplitude, limiting the effective bandwidth of the spectra when no tapering is applied.

Conversely, as the taper ratio is increased or the window shape becomes more like that of a 'cosine bell', the bandwidth increases, reducing the amount of leakage and giving rise to an increase in the resolution of closely-spaced low-frequency spectral components. The amplitudes of the Fourier spectra are significantly reduced, resulting in a clear H/V peak and a decrease of the spectral components towards lower frequencies.

Therefore, if the real spectrum contains a strong low-frequency component, cutting the time series into short time windows without tapering may strongly distort the observed spectrum. However, one should keep in mind that too much tapering may seriously impair the statistical efficiency of the estimates. In general, it is difficult to give precise recommendations which tapers to use in any specific situation (see, e.g., the discussion in Bingham et al., 1967). Yet, as these authors could show, it is recommendable to reduce the leakage more efficiently by increasing the length  $N$  of the time window and at the same time decreasing the taper ratio  $a$ , such that the length ( $Na$ ) of the cosine half-bells is kept constant.

Usually, a value of  $a = 5\%$  for window lengths of 30 s or 60 s is good enough for frequencies down to 0.2 Hz, whereas a further increase of the taper ratio  $a$  up to  $a = 20\%$  does not imply further changes in the spectra (see Figure 2).

For further readings, we refer to Harris (1978), Oppenheim et al. (1999) and Park et al. (1987).

**Figure 2** Effect of different cosine tapering for the same data set using a window length of 30 s. **Left column:** Thick lines show medium H/V spectral ratio plus/minus one standard deviation using (a) no tapering or cosine tapering with (b)  $a = 1\%$ , (c)  $a = 5\%$ , (d)  $a = 20\%$ . **Right column:** The corresponding Fourier spectra for both horizontal (continuous black and blue lines) and vertical (dashed line) components.

## 15.1 Introduction

### 15.1.1 The Treaty

The Comprehensive Nuclear-Test-Ban Treaty (CTBT) was opened for signature on 15 September 1996. The CTBT prohibits nuclear test explosions in all environments: underground, in the oceans, and in the atmosphere. As of 1 April 2011, the CTBT has been signed by 182 States, and has been ratified by 153 States. The CTBT will enter into force once it has been ratified by 40 States specified in Annex 2 of the treaty, the so called “Annex 2 States”. As of 1 April 2011, 35 of the Annex 2 States have ratified the CTBT.

The Comprehensive Nuclear-Test-Ban Treaty Organization Preparatory Technical Secretariat (CTBTO/PTS) was established in 1997 to prepare the systems for monitoring compliance with the CTBT once the Treaty enters into force. During this preparatory phase a great

amount of work is being done to establish the International Monitoring System (IMS), the Global Communication Infrastructure (GCI), the International Data Centre (IDC) in Vienna, Austria and the On-Site-Inspection (OSI) capabilities.

Fig. 15.1 shows a map with the countries who have as of April 2011 ratified, not ratified or not yet signed the Treaty.

**Fig. 15.1** Ratification status of the CTBT as of 1 April 2011.

### 15.1.2 Nuclear explosions

A nuclear explosion unleashes a tremendous amount of energy. Part of this energy can travel through the Earth, atmosphere, and oceans as seismic, infrasound, and hydroacoustic waves, respectively. The amount of energy travelling through each of these media is a function of where the explosion takes place, i.e., whether the explosion is underground, in the atmosphere, or underwater. The energy can also transfer from one media to another, depending on the site of the explosion. For example, an explosion on a boat will generate both infrasound and hydroacoustic signals, and the hydroacoustic signals can be converted into seismic signals.

A nuclear explosion also generates tremendous amounts of radioactive particles and gases, known as radionuclides. Observing these nuclides can provide unequivocal evidence that a nuclear explosion has occurred, since many of the radionuclides that can be detected and identified are fission products and can only arise from nuclear fission. Moreover, it is possible to distinguish between fission products from a nuclear explosion and those arising from atmospheric releases from civil nuclear power and reprocessing plants. The primary role of radionuclide monitoring is to provide unambiguous evidence of a nuclear explosion through

the detection and identification of fission products. These fission products can be sampled from ambient air as particulates or noble gases.

In addition to nuclear explosions, there are many other signals, which can be generated by other natural or man-made sources in the environments of interest. These include earthquakes, other non-nuclear explosions (e.g., mining explosions, quarries, accidental explosions), volcanic activity, airgun surveys, lightening, microbaroms, and biological sources (e.g., whales, elephants, etc.). Fortunately, not all of these sources generate signals similar to those generated by nuclear explosions.

Signals which are not of interest for CTBT purposes include repetitive sources (e.g., air gun surveys), very low energy events (e.g., lightening), signals outside the frequency range of interest (e.g., whale noise), signals outside the velocity range of interest, quickly moving objects (e.g., aircraft), and long, continuous signals (e.g., microbaroms). These distinguishing characteristics can be used to identify these signals as being noise during automatic processing, and are not considered further.

While signals from some sources can be discarded as noise, there is a wide range of sources which generate signals which must be processed, analyzed, and reviewed. The location and time of these sources are subsequently reported by the IDC in its bulletins. Potential sources in the bulletins include earthquakes, non-nuclear explosions, volcanoes, and meteorites. These sources may have similar characteristics of a nuclear explosion in terms of size, impulsive energy release, or frequency content.

Due to the nature of nuclear explosions and the environments in which they may take place, the IMS network was designed to have seismic, infrasound, hydroacoustic, and radionuclide sensors. The notional concept of monitoring the earth for a 1 kiloton nuclear explosion was used during the negotiations of the Treaty for illustrative purposes, and for comparisons between various proposed designs. This led to the design of the network in terms of number of stations, passband, and sensitivity. The provision for an onsite inspection following a suspicious event and its associated timelines as well as security concerns contributed to the timeliness requirements concerning IMS data acquisition and the issuance of IDC products.

While a nuclear weapon can be detonated in any environment, a clandestine test is most likely to take place underground. This is due to the fact that a nuclear explosion in the atmosphere would generate significant amounts of infrasound energy and copious quantities of radionuclides which would clearly indicate that a nuclear explosion took place. An underwater test would generate clear hydroacoustic signals as well as a release of radionuclides which would indicate a nuclear explosion.

Due to these reasons, environmental concerns, as well as to the Partial Test Ban Treaty (which prohibits nuclear weapon tests in the atmosphere, in outer space and under water), all nuclear explosions since 1980 have been underground. Since underground nuclear explosions generate significant seismic energy, seismic monitoring is particularly well suited for locating an underground nuclear explosion and determining its magnitude. The conversion of seismic magnitude to explosive yield is a complicated process, which relies on many different factors including geology and hydrology (e.g., Ringdahl, et al., 1992; Richards and Wu, 2011).

A number of techniques have been developed to discriminate between underground nuclear explosions and earthquakes (Bowers and Selby, 2009). Currently, the most effective

technique used at the IDC is the mb/Ms screening criterion, which relies on the fact that for an explosion and an earthquake with the same mb magnitude, the explosion will have a smaller Ms magnitude than the earthquake (see section 11.2.5.2 in Chapter 11, and Fig. 2 in Richards and Wu, 2011). Other criteria used for screening at the IDC consider event depth, the offshore location of an event, and regional seismic characteristics. Each of these criteria relies heavily upon seismic observations.

## 15.2 CTBTO networks

The International Monitoring System (IMS) is comprised of monitoring facilities as specified in the CTBT. The monitoring facilities are explicitly listed in the CTBT, and consist of 50 primary seismic stations and 120 auxiliary seismic stations, 11 hydroacoustic stations (6 hydrophone stations and 5 T-phase stations), 60 infrasound stations, and 80 radionuclide stations (80 stations capable of monitoring particulate radionuclides in the atmosphere, where 40 of those stations will be capable of monitoring for noble gases at the time the Treaty enters into force), and 16 radionuclide laboratories, which provide support activities.

The technical and operational requirements of each type of facility are specified in the appropriate IMS Operational Manual. Each new facility is certified and added to the IMS network once it is built and passes the certification process, in which it is demonstrated that it meets all technical specifications, including requirements for data authentication and transmission through the Global Communications Infrastructure (GCI) link to the IDC.

**Fig. 15.2** The complete IMS Network. The legend shows Primary Seismic (PS), Auxiliary Seismic (AS), Infrasound (IS), Hydroacoustic (HA), Radionuclide Particulate (RN (P)), Radionuclide Noble Gas (RN (NG)), and Radionuclide Laboratory (RN LAB) facilities.

### 15.2.1 Seismic station

A seismic station has three basic parts; a seismometer to measure the ground motion, a recording system which records the data digitally with an accurate time stamp, and a communication system interface.

Within the primary and auxiliary seismic networks, there are two types of seismic stations, three-component (3C) stations and array stations. The primary seismic network is mostly composed of arrays (30 arrays out of 50 stations), whereas the auxiliary seismic network is mostly composed of 3 C stations.

As of 1 April 2011 42 primary seismic and 99 auxiliary seismic stations have been certified. The specifications for primary and auxiliary seismic stations are summarized in Tab. 15.1.

#### 15.2.1.1 Three-component station

A three-component seismic station requires recording of broadband ground motion in three orthogonal directions. This type of recording can be done using either a single three-component broadband seismometer that covers the combined long-period and short-period frequency ranges, or with separate long-period and short-period seismometers (see DS 5.1).

#### 15.2.1.2 Array station

An IMS seismic array station consists of multiple short-period seismometers and three-component broadband instruments. Some existing short-period arrays also have associated multiple long-period seismometers. Both short-period and long-period seismometers are typically deployed in a geometrical configuration designed to allow ground motion signals to be combined to enhance the signal-to-noise ratio (see Chapter 9). New arrays should contain at least 9 vertical short-period elements and at least one three-component broadband element. The broadband element can use a single broadband instrument or one three-component short-period instrument with one three-component long-period instrument (see Tab. 15.1).

A teleseismic array is a seismic array designed for optimum detection and slowness estimation of seismic phases from sources at distances greater than 3000 kilometres. The distances between the array sensors are typically between 1000 and 3000 metres, and the total aperture is up to 60 kilometres.

A regional array is a seismic array designed for optimum detection and slowness estimation of seismic phases from sources at distances less than 3000 kilometres. The distances between array sensors are typically between 100 and 3000 metres, and the total aperture is up to 5 kilometres.

Primary seismic stations send continuous near-real-time data to the International Data Centre. Auxiliary seismic stations provide data upon request from the International Data Centre. In order to provide information on their operational state, in addition to ground motion data, seismic stations transmit state-of-health information such as:

- Clock status, to indicate whether the clock is synchronized to Coordinated Universal Time.

- Calibration status, to indicate whether a calibration signal is on or off.
- Vault/borehole status, to indicate whether the lid or door of the equipment vault or borehole is closed or open as a data surety measure

**Tab. 15.1** Specifications for primary and auxiliary seismic stations (minimum requirements; from CTBT/PC/II/Add.2 16 May 1997, p.43).

| CHARACTERISTICS                                           | MINIMUM REQUIREMENTS                                                                                                   |
|-----------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------|
| <i>Sensor type</i>                                        | Seismometer                                                                                                            |
| <i>Station type</i>                                       | Three-component or array                                                                                               |
| <i>Position (with respect to ground level)</i>            | Borehole or vault                                                                                                      |
| <i>Three-Component Passband</i> <sup>1</sup>              | Short-period: 0.5 to 16 Hz plus Long-period: 0.02 to 1 Hz or Broadband: 0.02 to 16 Hz                                  |
| <i>Sensor response</i>                                    | Flat to velocity or acceleration over the passband                                                                     |
| <i>Array Passband</i>                                     | (Short-period: 0.5 to 16 Hz<br>Long-period: 0.02 to 1 Hz) <sup>2</sup>                                                 |
| <i>Number of sensors for new arrays</i> <sup>3</sup>      | 9 short-period (one component) plus 1 short-period (three component) plus 1 long-period (three component) <sup>4</sup> |
| <i>Seismometer noise</i>                                  | ≤ 10 dB below minimum-earth noise at the site over the passband                                                        |
| <i>Calibration</i>                                        | Within 5% in amplitude and 5 degrees in phase over the passband                                                        |
| <i>Sampling rate</i>                                      | ≥ 40 samples per second <sup>5</sup><br>Long-period: ≥ 4 samples per second                                            |
| <i>System Noise</i>                                       | ≤ 10 dB below the noise of the seismometer over the passband                                                           |
| <i>Resolution</i>                                         | 18 dB below the minimum local seismic noise                                                                            |
| <i>Dynamic range</i>                                      | ≥ 120 dB                                                                                                               |
| <i>Absolute timing accuracy</i>                           | < 10 ms                                                                                                                |
| <i>Relative timing accuracy</i>                           | < 1 ms between array elements                                                                                          |
| <i>Operation temperature</i>                              | -10 °C to + 45 °C <sup>6</sup>                                                                                         |
| <i>State of health</i>                                    | Status to be transmitted to the International Data Centre: clock, calibration, vault and/or borehole status, telemetry |
| <i>Delay in transmission to International Data Centre</i> | < 5 minutes                                                                                                            |
| <i>Data frame length</i>                                  | Short-period: < 10 seconds; long-period: < 30 seconds                                                                  |

<sup>1</sup> For existing Global Telemetered Seismic Network stations, upgrading needs further consideration.

<sup>2</sup> For one-component element of teleseismic arrays, the upper limit is 8 Hz.

<sup>3</sup> In case of noisy sites or when increased capability is required, number of sensors could be increased.

<sup>4</sup> Can be achieved by a single broadband instrument.

<sup>5</sup> This applies to three-component and regional arrays. For existing teleseismic arrays, 40 samples per second are necessary for three-component but 20 samples per second are suitable for other sensors.

<sup>6</sup> Temperature range to be adapted for some specific sites.

## 15.2.2 Hydroacoustic station

In order to detect the acoustic energy ducted through the SOFAR channel a network composed of 11 hydroacoustic stations is being implemented. Six stations will be equipped with hydrophones. The other five hydroacoustic stations are located on steep-sloped islands and will make use of seismic sensors to detect the waterborne energy which is converted to a seismic wave at the boundary of the island. This type of propagation has long been known to the seismic community as T-phase propagation. T-phase stations are not as effective in detecting and identifying hydroacoustic signals from explosions, but they are considerably cheaper than hydrophone stations. The mixture of hydrophone and T-phase stations selected for the IMS hydroacoustic network was chosen as a cost-effective compromise. As of 1 April 2011 10 hydroacoustic stations have been certified.

An International Monitoring System hydroacoustic station can consist of either ocean-deployed hydrophone sensors and data acquisition systems, referred to herein as a *Hydrophone Station*, or one or more island-deployed seismometer sensors and data acquisition systems, referred to herein as a *T-phase Station*. There are 6 hydrophone stations and 5 T-phase stations.

### 15.2.2.1 Hydrophone station

A hydrophone station consists of an underwater segment and a data acquisition segment. When the hydrophone station is located on an island, two distinct cables and hydrophone sensors are deployed nominally off opposite shores. The hydrophone sensor elements are placed at or near the axis of the Sound Fixing and Ranging (SOFAR) channel, using a subsurface float and an ocean-bottom anchor. Each cable has three sensors with electronics for digitizing the signal. In order to provide the station with some directional capabilities, the three hydrophones are placed in a triangular configuration and each sensor is separated horizontally by a distance of approximately 2 kilometers. A single cable is used to bring the signals from the hydrophone sensors to shore. Hydrophone locations are selected considering

<sup>1</sup> Procedures for buffering to ensure minimum loss of data and single point failure should be addressed in the International Monitoring System Operational Manual.

the best combination of these factors: local optimum of low noise, wide viewing azimuth, and ease of cable installation.

All hydrophone stations, except for Cape Leeuwin, are located on relatively small islands. They generally consist of two undersea trunk cables, each with three hydrophones sensors. To avoid bathymetric blockage, by the island, cables and sensors are deployed on opposite shores of the island. Each hydrophone sensor has an independent wet-end digitizer. The digital signals are transmitted to the shore facility via a non-repeated fiber optic cable for processing and transmission to the IDC in Vienna. The (minimum requirement) specifications for hydrophone stations are summarized in Tab. 15.2.

**Tab. 15.2** Specifications for IMS Hydrophone Stations (minimum requirements; from CTBT/PC/II/Add.2 16 May 1997, p.46)

### 15.2.2.2 T-phase station

A T-phase station consists of one or more seismometers and one or more data acquisition systems. The T-phase station is sited near the shore of small islands with steep bathymetry in order to detect seismic waves generated by the coupling of waterborne energy along the flanks of the island. Each T-phase station location is chosen to provide as large an azimuthal monitoring coverage as possible while minimizing the background seismic noise level. Up to three T-phase seismometer systems may be required at different island locations to provide full azimuthal monitoring coverage. For specifications of T-phase stations see Tab. 15.3.

**Tab. 15. 3** Specifications for IMS T-phase stations (minimum requirements; from CTBT/PC/II/Add.2 16 May 1997, p.45)

### 15.2.3 Infrasound station

An infrasound station consists of an array of 4 up to 15 elements; typical designs have 4 to 8 elements. Each array element has three basic parts: 1) a microbarometer connected to a wind noise reduction system to measure the infrasound signals, 2) a recording system to record digital data with an accurate time stamp, and 3) a communication system interface.

A typical infrasound station is designed for infrasound signals detection along with slowness and azimuth estimation in the frequency regime of 0.02 to 4 Hz. The arrays are usually shaped either, as irregular triangles with an internal element or an inner sub-array, or as pentagons with a triangular inner sub-array. The aperture of the main arrays (outer) varies between 1 and 3 km while the sub-arrays (inner) usually have an aperture of 100 to 300 m.

The total number of the arrays in the IMS infrasound network is 60. As of 1 April 2011, 43 stations are installed. All the stations in the IMS infrasound network are new and are or will be constructed under the IMS program. All the infrasound stations send continuous near-real-time data to the International Data Centre, in Vienna.

In order to provide information on their operational status, in addition to micropressure data, infrasound stations transmit also state-of-health information, such as:

- Clock status, to indicate whether the clock is synchronized to Coordinated Universal Time.
- Vault status, to indicate whether the lid or door of the equipment vault is closed or open as a data surety measure

The minimum requirements for the installation and certification of an infrasound station are summarized in Tab. 15.4.

**Tab. 15.4** Specifications for IMS Infrasound Stations (minimum requirements; from CTBT/PC/II/Add.2 16 May 1997, p. 47)

| CHARACTERISTICS                  | MINIMUM REQUIREMENTS                           |
|----------------------------------|------------------------------------------------|
| <i>Sensor type</i>               | Microbarograph                                 |
| <i>Number of sensors</i>         | 4-element array <sup>1</sup>                   |
| <i>Geometry</i>                  | Triangle with a component at the centre        |
| <i>Spacing</i>                   | Triangle basis: 1 to 3 km <sup>2</sup>         |
| <i>Station location accuracy</i> | $\leq 100$ m                                   |
| <i>Relative sensor location</i>  | $\leq 1$ m                                     |
| <i>Measured parameter</i>        | Absolute <sup>3</sup> or differential pressure |
| <i>Passband</i>                  | 0.02 to 4 Hz                                   |

|                                                     |                                                  |
|-----------------------------------------------------|--------------------------------------------------|
| <i>Sensor response</i>                              | Flat to pressure over the passband               |
| <i>Sensor noise</i>                                 | ≤18 dB below minimum acoustic noise <sup>4</sup> |
| <i>Calibration</i>                                  | <5% in absolute amplitude <sup>5</sup>           |
| <i>State of health</i>                              | Status data transmitted to the IDC               |
| <i>Sampling rate</i>                                | ≥10 samples per second                           |
| <i>Resolution</i>                                   | ≥1 count per 1 mPa                               |
| <i>Dynamic range</i>                                | ≥108 dB                                          |
| <i>Timing accuracy</i>                              | ≤1 msec                                          |
| <i>Standard temperature range</i>                   | -10 °C to +45 °C <sup>6</sup>                    |
| <i>Buffer at station or at National Data Centre</i> | ≥7days                                           |
| <i>Data format</i>                                  | Group of Scientific Experts format               |
| <i>Data frame length</i>                            | ≤30 seconds                                      |
| <i>Data transmission</i>                            | Continuous                                       |
| <i>Data availability</i>                            | ≥98%                                             |
| <i>Timely data availability</i>                     | ≥97%                                             |
| <i>Mission capable array</i>                        | ≥3 elements operational                          |
| <i>Acoustic filtering</i>                           | Noise reduction pipes (site dependent)           |
| <i>Auxiliary data</i>                               | Meteorological data <sup>7</sup>                 |

<sup>1</sup> In case of noisy sites or when increased capability is required, number of components could be increased.

<sup>2</sup> 3 km is the recommended spacing

<sup>3</sup> Used for daily state of health.

<sup>4</sup> Minimum noise level at 1 Hz : ~ 5 mPa

<sup>5</sup> Periodicity: once per year (minimum).

<sup>6</sup> Temperature range to be adapted for some specific sites.

<sup>7</sup> Once per minute (minimum).

#### 15.2.4 Radionuclide particulate station

Among the monitoring technologies in the IMS network, radionuclide monitoring is the only technique that provides the forensic or confirmatory evidence that a detected explosion is nuclear in nature. . Eighty radionuclide stations are being established in the IMS for sampling and radionuclide analysis of airborne particulates. Forty of these stations will also have the capability for sampling and analysis of noble gases. The radionuclide network was designed to achieve a detection capability of not less than 90% within approximately 14 days (including 3 days reporting time) for a 1 kt nuclear explosion in the atmosphere or from venting by an underground or underwater detonation.

Following a nuclear explosion, the radioactive materials released consist mainly of fission products and neutron activation products (from the interaction of the neutrons released during fission with elements in the device and surrounding materials). For particulate samples, there are 84 fission and neutron activation products which are regarded as relevant to CTBT. From their relative abundance or mutual ratios in the sample, it will be possible to determine whether they are from a nuclear explosion or other possible sources of radioactivity such as nuclear power or reprocessing plants.

In a radionuclide particulate station, at least 12,000 m<sup>3</sup> of air is pumped daily through a filter with high collection efficiency in order to produce a large volume of air sample for high detection sensitivity. This sample is then analyzed using high-resolution gamma-ray spectrometry since the fission products and neutron activation products are gamma-emitters. The data is directly transmitted to the IDC thru the GCI for processing, analysis and review.

The main components of a radionuclide particulate station are:

- High-volume air- sampler – for collection of large volume of airborne particulates or aerosols;
- Filter material - for trapping particulates with high efficiency; after sampling, this is compressed or cut into a geometry best suited for gamma spectrometry;
- Detection equipment – high-purity germanium crystal with good resolution, high efficiency and encased inside lead shielding to reduce background radioactivity;
- Multi-channel analyzer, computer system, station operation software - for production of spectral raw data for transmission to the IDC for analysis and operation of the system;
- State-of-health (SOH) sensors - status of station monitors, i.e., air flow rate, detector temperature, indoor temperature and humidity, filter position monitor, power supply status, lead shield status, that could be used to interpret the measured radionuclide data and provide an indication of normal and secure operation;
- Meteorological sensors - meteorological data monitors, i.e., precipitation, temperature, wind speed, wind direction;
- Very small aperture antenna (VSAT) - for transmission of data to IDC via satellite;
- Uninterruptible power supply and auxiliary generator - for power stability and alternate source of electrical power.

There are two types of radionuclide particulate stations: (1) manual station which requires an operator to perform the daily operations such as filter change and preparation, and (2) automatic station. The two types of automatic systems in the IMS network are the Radionuclide Aerosol Sampler/Analyzer (RASA) and Automatic Radionuclide Air Monitoring Equipment (ARAME). The minimum technical requirements for certification of a particulate station are listed in Tab. 15.5.

**Tab. 15.5** Specifications for IMS Radionuclide Particulate Stations (minimum requirements; from CTBT/PC/II/Add.2 16 May 1997, p. 48)

| CHARACTERISTICS        | MINIMUM REQUIREMENTS               |
|------------------------|------------------------------------|
| <i>System</i>          | Manual or automated                |
| <i>Airflow</i>         | 500 m <sup>3</sup> h <sup>-1</sup> |
| <i>Collection time</i> | 24 h                               |
| <i>Decay time</i>      | ≤ 24 h                             |

|                                                         |                                                                                                                     |

| <i>Auxiliary data</i>                                   | Meteorological data<br>Flow rate measurement every 10 minutes                                                       |
| <i>Data availability</i>                                | $\geq 95\%$                                                                                                         |
| <i>Down time</i>                                        | $\leq 7$ consecutive days<br>$\leq 15$ days annually                                                                |

As of 1 April 2011, of the 80 radionuclide stations which comprise the IMS radionuclide particulate network, 60 have been certified as meeting the requirements above.

### 15.2.5 Radionuclide noble gas station

For underground or underwater nuclear explosions, the radioactive materials with greater probability of being vented and released into the atmosphere are noble gases rather than particulates. Noble gases are chemically inert and will not be attached to its surrounding environment; thus these can leak from an underground cavity through vents or cracks or be transported from underwater to the surface. Once in the atmosphere these remain gaseous, travel long distances and unlike particulates, are not washed out by precipitation. . Among the noble gases likely to be released into the atmosphere following a nuclear explosion, radioactive xenon isotopes (radioxenons) are presently the most suitable for monitoring purposes. They are produced with a relatively high yield in nuclear explosions and have suitable half-lives. By examining the ratios of xenon isotopes in a sample, it is possible to distinguish whether the radioxenons detected are from a nuclear explosion or other civilian applications such as nuclear reactor releases. The 4 radioxenons monitored by the noble gas stations are  $^{131\text{m}}\text{Xe}$ ,  $^{133\text{m}}\text{Xe}$ ,  $^{133}\text{Xe}$  and  $^{135}\text{Xe}$ , which are beta (or conversion electron) and gamma emitters. The technology for sampling and analysis of noble gas under field conditions is less mature and more complex than that for particulates. Thus, the noble gas

systems have been tested and evaluated under the International Noble Gas Experiment (INGE) conducted by the Technical Secretariat.

In a noble gas station, the air sample collected undergoes processing to separate and concentrate xenon from other constituents. The activity of the purified/concentrated radionuclides is then measured by high-resolution gamma-ray spectrometry or beta-gamma coincidence counting. The volume of air analyzed is determined from the volume of non-radioactive xenon (stable xenon), taking into account the natural abundance of xenon in air (0.087 ppmV at STP). Stable xenon is measured using gas chromatography or thermal conductivity detector.

The three types of noble gas systems in the IMS network, all of which operate automatically are: (1) SPALAX (Système de Prélèvement Atmosphérique en Ligne avec l'Analyse du Xénon) (2) SAUNA (Swedish Automatic Unit for Noble Gas Acquisition) and (3) ARIX (Analyzer of Radioactive Isotopes of Xenon). The SPALAX uses high-resolution gamma-ray spectrometry while the SAUNA and ARIX use beta-gamma coincidence counting.

The minimum technical requirements for certification of noble gas stations are listed below in Tab. 15.6.

**Tab. 15.6** Specifications for IMS Radionuclide Noble Gas Stations (minimum requirements; CTBT/PC/II/Add.2 16 May 1997, p. 49)

| CHARACTERISTICS                                      | MINIMUM REQUIREMENTS                                                         |

As of 1 April 2011, there are 27 noble gas stations installed out of the 40. Certification started in 2010, with 3 noble gas stations certified as meeting the abovementioned requirements.

<sup>1</sup> Smallest concentration of radioactivity in a sample that can be detected with a 5% probability of erroneously detecting radioactivity, when in fact none was present (Type I error) and also, a 5% probability of not detecting radioactivity, when in fact it is present (Type II error).

## **15.2.6 Radionuclide laboratories**

In accordance with the CTBT, the network of radionuclide monitoring stations is supported by 16 radionuclide laboratories which perform re-analysis of samples from stations. The purpose of re-analysis of samples from stations by a laboratory is: (1) to corroborate the results of the routine analysis of a sample from an IMS station, in particular to confirm the presence of fission products and/or activation products; (2) to provide more accurate and precise measurements; and (3) to clarify the presence or absence of fission products and/or activation products in the case of a suspect or irregular analytical result from a particular station (CTBT/WGB/TL-11, 17-18 /Rev. 4).

These laboratories have a quality system to include sample handling, preparation, measurement, data analysis and reporting. Their software enables data transmission to the IDC in a standardised format. The Technical Secretariat organizes annual proficiency test or intercomparison exercises as part of a quality assurance program. These laboratories are certified by the Technical Secretariat according to rigorous management and technical requirements contained in PTS/INF.96 Rev. 7. As of 1 April 2011, ten of the 16 radionuclide laboratories are certified.

## **15.3 Data acquisition**

### **15.3.1 Introduction**

The stations in the IMS network send data to the International Data Centre (IDC) according to the Formats and Protocols specified in the corresponding IMS Operational Manual. Stations in the primary seismic, hydroacoustic, and infrasound networks send data in Continuous Data (CD) format. As the name implies, data from these stations are sent continuously to the IDC.

Stations in the auxiliary seismic network send data to the IDC in response to a data request received from the IDC. Each data request is formulated based on IDC data processing results from stations in the primary seismic, hydroacoustic, and infrasound networks. Consequently, only segments of data from auxiliary seismic stations are sent to the IDC. Radionuclide stations send data to the IDC on a regular daily schedule as the data become available at the station.

All IMS data received at the IDC are parsed and are accessible through the IDC relational database management system (RDBMS). After the data are stored in the RDBMS, they are available for automatic processing.

All stations in the IMS network can be securely managed using command and control messages. The communication between IMS stations and the IDC, and between the IDC and users is done over the Global Communications Infrastructure (GCI).

### **15.3.2 Security concerns**

The security concerns of the IMS data are addressed in the following ways. Data collected at IMS stations are signed with a private key, and the resulting signature from that process is

transmitted along with the data. The recipient of the data can then use the data, the signature, and the public key from the station to authenticate the data. If the data passes this authentication process, it means that the data were signed by the private key at the station, and that the data have not been modified.

The private key is stored in a hardware device, and with tamper resistant features. Any attempt to tamper with the private key is reported.

The private and public keys are issued and maintained using a Public Key Infrastructure (Xenitellis, 2000), which is operated and maintained by CTBTO. This process of authentication and verification is also used for command and control messages, which are elaborated in section 3.6.

### **15.3.3 Continuous data stations**

Primary seismic, hydroacoustic, and infrasound stations send data to the IDC in Continuous Data (CD) format. At present there are two versions of CD format, namely CD-1.0 format and CD-1.1 format. Both are currently in use, but all new stations employ CD-1.1 format.

The data completeness and timeliness requirements for continuous data stations are quite stringent. These stations are required to send at least 98% of all expected data to the IDC, and 97% of the data should be received at the IDC within 5 minutes after the data have been recorded at the station. Consequently, after any type of outage of sending data, it is very important to restore the real time data flow to the IDC in order to meet the timeliness requirement. Consequently, the CD format specifies a Last In First Out (LIFO) sequence of sending data after an extended outage. This means that the newly recorded data are sent first, which can be interspersed with older data, progressing from younger data to older data.

CD protocol is based on socket level communication. The data sender initiates the data flow by sending a Connection Request Frame to the receiver's well known port and IP address. The receiver responds by sending a Port Assignment Frame to the sender, which specifies the IP address and port where the sender should begin sending data. In case of CD-1.1 format, there is additional exchange of Option Request Frames at this stage.

The sender then begins to send the data to the receiver at the specified IP address and port. In case of CD-1.0, this consists of a Data Format Frame (DFF), which specifies the format of the subsequent Data Frames (DF). All DFs will adhere to the format specified in the DFF, and can only be interpreted with the DFF information. If there is a change of format, for example if a channel is added or removed from the DF, then a new DFF, preceded by an Alert Frame, must be sent by the sender. The data flow can be terminated by either party by sending the appropriate Alert Frame.

The fact that the data format information is only sent once in CD-1.0 format leads to an efficient use of communication bandwidth. However, it also means the Data Frames can only be interpreted with information from the corresponding Data Format Frame. In order to address this shortcoming, and to add additional functionality, CD-1.1 format was created.

In the case of CD-1.1 format, the Option Request Frames are exchanged after the Port Assignment Frame is sent to the sender, as mentioned above. The sender will then begin to

send Data Frames (DF). In CD-1.1, each DF fully describes the data, so there is no need for Data Format Frames, as is required for CD-1.0 format. The CD-1.1 Data Frames also contain a sequence number, which can be used to record which frames have been sent and received. The receiver and sender exchange Acknack Frames to synchronize this information. Every frame in CD-1.1 format can also be signed, to ensure integrity of the data.

CD-1.1 format also include the capability for Command and Control Frames, which can be used to manage IMS stations. More information concerning Command and Control can be found in Section 3.6.

In both CD-1.0 and CD-1.1 the Data Frame contains Channel Sub-Frames (CSF), where each CSF contains the data from a particular data channel or sensor. For example, a typical three component station will have three CSFs, with one CFS for each of the three channels BHZ, BHN, and BHE. The waveform data in each CSF is signed, and the resulting signature is also stored in the CSF. In the case of CD-1.1, the entire data frame will also be signed, and the signature of the entire frame will be sent in the frame trailer. The components of a CD-1.1 Data Frame are summarized in Fig. 15.3.

|                                                |                  |
|------------------------------------------------|------------------|
| Frame Header<br>and<br>Channel Subframe Header |                  |
| Channel Subframe 1                             | <i>signature</i> |
| Channel Subframe 2                             | <i>signature</i> |
| ...                                            |                  |
| Channel Subframe n                             | <i>signature</i> |
| Frame Trailer                                  | <i>signature</i> |

**Fig. 15.3** Components of a CD-1.1 Data Frame. Note that each channel subframe is signed, as well as the frame itself. The data frame signature is found in the frame trailer.

### 15.3.4 Segmented data stations

IMS auxiliary seismic stations send data to the IDC in response to a waveform data request from the IDC. The data request and the response adhere to IMS 2.0 Formats and Protocol. The request specifies the start and end time, as well as the station and channels which should be returned to the requestor.

The data request is based on a preliminary event location made using data from primary stations, i.e., stations which send data in continuous mode. Once an event is detected by the primary network, a data request is sent to all auxiliary stations within 30 degrees of this preliminary location plus auxiliary stations which have a high probability of detecting the

event. In this way, the auxiliary data assist in refining the location by providing additional regional observations.

The messages exchanged in IMS 2.0 format are sent via e-mail. The original concept of using email for waveform data exchange was pioneered by Urs Kradolfer (Kradolfer, 1996). Prior to IMS 2.0, there were a number of earlier revisions of the format, including GSE 2.0, GSE 2.1, and IMS 1.0 (see also Chapter 10 and IS 10.1 and 10.2). While additional data types and features have been added with each revision, the data request and response messages have remained relatively stable.

Since IMS 2.0 data are typically sent via email, the waveform data are converted into ASCII representation in the email message. There are a few different supported waveform data types. One data type is integer format, named “INT”, where the waveform digital counts are reported as integer values. The second format is named “CM6”, where the digital waveform counts are processed with an algorithm to compress the data and transmit the data in ASCII format. A third option allows waveform data to be sent along with corresponding data signatures. This format is named “CSF”, and is formed by converting a CD-1.1 Channel Sub-Frame (see Section 3.3), into ASCII format using base 64 encoding.

### **15.3.5 Radionuclide stations**

Radionuclide stations send data to the IDC on a regular daily schedule as the data become available at the station. The data are sent in IMS 2.0 format via e-mail. Particulate systems produce one radionuclide spectrum per day which is sent to the IDC. Noble Gas systems produce one or two radionuclide spectrum per day, depending on the type of measurement system. In addition, radionuclide stations send state of health information on a regular basis, ranging from 2 to 6 hours, depending on the type of system. Radionuclide stations also send various spectra types for calibration purposes, including blank spectra, detector background spectra, and calibration source spectra.

### **15.3.6 Command and control**

Command and Control messages are used to securely command IMS stations. The process is typically initiated by sending a signed command message from the IDC to the station. At the station the command is checked for authenticity, the requested action is carried out, and a command response message is returned to the IDC. The commands are used for seismic station calibration. Command messages are sent in IMS 2.0 format via email. There are also provisions in CD-1.1 format to support the exchange of command and control frames.

### **15.3.7 Global Communication Infrastructure**

Data are sent from the IMS stations to the IDC over the Global Communication Infrastructure (GCI). The GCI is also used to send IMS data and IDC products from the IDC to authorized users. The topology between stations and the IDC is typically done in one of two ways; one option is basic topology, and the other is the Independent Sub Network (ISN).

In the case of basic topology, data are sent from the station over a Very Small Aperture Terminal (VSAT) through a satellite link to a satellite ground station, which in turn is connected to the IDC via a terrestrial link. In the case of an ISN, a country may take the responsibility to transport data from several stations on its territory to a central location. The data at that central location are then sent onward to the IDC, typically over a terrestrial connection.

The complete GCI is a large operation which includes 215 VSAT connections and 6 terrestrial connections. The GCI link availability requirement is 99 %, which is currently being routinely achieved.

## 15.4 Waveform data processing

### 17,4.1 Introduction

Waveform data are automatically processed once they have arrived at the IDC. Waveform station processing for continuous data stations is done in fixed time intervals (Fig. 15.4). The duration of those time intervals is 10 minutes for primary seismic and hydroacoustic stations, and 30 minute intervals for infrasound stations. Each interval is processed after 95 % of data used for station processing from that station has arrived in the RDBMS. Data from auxiliary seismic stations are processed once the requested data segments have been parsed into the RDBMS and a sufficient amount of requested data has been received.

**Fig. 15.4** Overview of station processing and network processing. Note that network processing is run three times, to accommodate data from auxiliary stations and late arriving data. Network processing results in the Standard Event Bulletins (SEL) 1, 2, and 3, which are automatically generated 1, 3, and 6 hours after real time.

Waveform station processing performs quality control checks, band-pass filtering and beamforming (see Chapters 4 and 9) to improve the signal-to-noise ratio and detect signals in the data interval. Feature extraction is then performed for each detection and the resulting detection time (see also Chapter 16), amplitude, period, azimuth and slowness are written to the RDBMS. The final stages of station processing include signal grouping, initial phase

identification, and location of single station events. The arrivals resulting from station processing are the input in network processing, where the arrivals are combined to form events which are published as automatic bulletins, named SEL1, SEL2, and SEL3 where SEL is an abbreviation for Standard Event List.

After the final automatic bulletin is produced, the data are ready for review by the IDC analysts. The analysts correct mistakes in the automatic bulletin, refine the results, and add events which were missed. The result of this work is published as the Reviewed Event Bulletin (REB). Currently, during provisional operations, the target timeline for publishing the REB is within 10 days of real time. After Entry Into Force (EIF) of the Treaty, the target timeline is reduced to 48 hours.

## 15.4.2 Seismic station processing

Broadly speaking, there are three types of IMS seismic stations; three component stations, array stations (which typically vary in aperture up to 20 kilometers), and one large array, which has an aperture of more than 60 kilometers. Different processing techniques are applied to these three station types, as described below.

Station processing is performed by a series of two applications, DFX (**D**etection and **F**eature **E**xtraction) and StaPro (**S**tation **P**rocessing). DFX is used to detect signals and extract their features. The output of DFX includes detection time, amplitude, period, signal to noise ratio (SNR), azimuth, azimuth uncertainty, slowness, and slowness uncertainty. The StaPro application recognizes noise arrivals, assigns initial phase names, and locates single station events. The output of StaPro includes the initial phase name and single station event locations.

### 15.4.2.1 DFX

DFX performs the following processing steps:

1. Data Quality Control (DQC) – removes bad channels, repairs data gaps and spikes;
2. Improve and Estimate SNR – performs filtering and beaming to improve SNR for all detection beams;
3. Find detection – use STA/LTA detector (see IS 8.1), best beam and trigger time;
4. Refine time – use Akaike Information Criteria (AIC) to refine onset time;
5. Measure amplitude and period;
6. Estimate azimuth and slowness – perform frequency-wavenumber (f-k) (cf. Chapter 9) or polarization analysis (see Fig. 2.6 of Chapter 2) to estimate slowness, azimuth, and associated error estimates;
7. In the case of array data, steps 4 and 5 are repeated, based on the results from step 6.

#### ***Data Quality Control***

Data Quality Control (DQC) is the initial step in data processing. Problematic data are identified as spikes, continuous zeros, repeated amplitude values, gaps, and channels with anomalous amplitude values. Spikes are recognized by the difference in amplitude relative to the surrounding data values. Repeated amplitude values are recognized by the number of consecutive samples with the same amplitude value (usually between 4 and 10). In some cases, problematic data can be repaired through interpolation, or detrending. If the data cannot

be repaired, then a mask is created indicating where the data have quality problems and should be excluded from processing. If a large percentage of the data (usually more than 33%) on a given channel are masked, then the channel is excluded from processing for the entire processing interval. Recall that processing intervals are typically 10 minutes long for seismic data.

### ***Improve and estimate SNR***

The SNR is improved at three component stations by filtering the vertical channel in various filter bands, and incoherent beams are made from the two horizontal channels. An example beam recipe for a three component station is shown in Fig. 15.5 and the filtered vertical channel at the station SIV is shown in Fig. 15.6.

An array station consists of sensors which are spatially distributed. When a signal traverses an array, it is recorded by individual sensors at different times. Time delays relative to the reference beam point can be calculated by using the relative distance to the reference point, and an assumed slowness vector (Fig. 15.7). Based on the coherence of the signal and the incoherence of noise, beaming delay-corrected signals from array elements can significantly improve the SNR of a signal.

### **Typical beam recepies for 3-C stations:**

| name  | type | rot | std | snr  | azi | slow  | phase | flo  | fhi  | ford | zp | ftype | group      |
|-------|------|-----|-----|------|-----|-------|-------|------|------|------|----|-------|------------|
| Z0515 | coh  | no  | 0   | 3.50 | 0.0 | 0.000 | -     | 0.50 | 1.50 | 3    | 0  | BP    | vertical   |
| Z1020 | coh  | no  | 0   | 3.50 | 0.0 | 0.000 | -     | 1.00 | 2.00 | 3    | 0  | BP    | vertical   |
| Z1530 | coh  | no  | 0   | 4.00 | 0.0 | 0.000 | -     | 1.50 | 3.00 | 3    | 0  | BP    | vertical   |
| Z2040 | coh  | no  | 0   | 4.00 | 0.0 | 0.000 | -     | 2.00 | 4.00 | 3    | 0  | BP    | vertical   |
| Z3060 | coh  | no  | 0   | 5.00 | 0.0 | 0.000 | -     | 3.00 | 6.00 | 3    | 0  | BP    | vertical   |
| Z4080 | coh  | no  | 0   | 6.00 | 0.0 | 0.000 | -     | 4.00 | 8.00 | 3    | 0  | BP    | vertical   |
| H0515 | inc  | no  | 0   | 5.50 | 0.0 | 0.000 | -     | 0.50 | 1.50 | 3    | 0  | BP    | horizontal |
| H1020 | inc  | no  | 0   | 5.50 | 0.0 | 0.000 | -     | 1.00 | 2.00 | 3    | 0  | BP    | horizontal |
| H1530 | inc  | no  | 0   | 5.50 | 0.0 | 0.000 | -     | 1.50 | 3.00 | 3    | 0  | BP    | horizontal |
| H2040 | inc  | no  | 0   | 5.50 | 0.0 | 0.000 | -     | 2.00 | 4.00 | 3    | 0  | BP    | horizontal |
| H4080 | inc  | no  | 0   | 5.50 | 0.0 | 0.000 | -     | 4.00 | 8.00 | 3    | 0  | BP    | horizontal |

**Fig. 15.5** Example of a beam recipe for a three component station. The column headings are: name – channel name for the beam; type – beam type, coh – coherent or inc – incoherent; std – specifies whether or not this is a standard beam (1 if yes); snr – threshold snr for declaring a detection; azi – azimuth to use for beamforming at an array; slow – slowness to use for beamforming at an array; phase – phase to use for beamforming when making origin beams; flo – low cut value of the applied Butterworth filter; fhi – high cut value of the applied butterworth filter; ford – specifies the order of the applied Butterworth filter; zp – specifies if the applied Butterworth filter should be zero phase (1 if yes); ftype - filter of the applied Butterworth filter (BP – band pass; HP – high pass; LP – low pass); group – specifies which channels from the station should contribute to forming the beam.

**Fig. 15.6** Filtered (1.0 to 2.0 Hertz) vertical channel from the station SIV, in San Ignacio, Bolivia for arrival at 01:55:38.9 for event on 09-Oct-2006 resulted in a good signal-to-noise ratio (lower trace), in comparison with the more broadband velocity raw data (upper trace).

**Fig. 15.7** Illustration of a seismic plane wave passing through an array.

For each IMS array, there are several beams which are created, where each beam specifies a specific azimuth and slowness to steer the beam, specific filter band, and a list of which elements to use to form the beam. A beam recipe for an array station uses the same format as for 3-component stations, as was shown in Fig. 15.5.

### **Find detection**

An STA/LTA detector is used at the IDC for detecting signals in seismic data. STA (short-term-average) is a time-average of some function of data (for example, amplitude, power, or energy) over a short period of time relative to the LTA (long-term-average) (see IS 8.1). The STA/LTA detector for seismic and hydroacoustic data uses a running average for the STA and a recursive average for the LTA. The LTA “lags” the STA in time by half the width of the STA window. The STA and LTA are defined as:

$$\text{STA:} \quad \text{STA}(k) = \text{STA}(k-1) + \frac{1}{S} [ |x(k + \frac{S}{2})| - |x(k-1 - \frac{S}{2})| ]$$

$$\text{LTA:} \quad \text{LTA}(k) = (1 - \frac{1}{L})\text{LTA}(k-1) + \frac{1}{L} \text{STA}(k - S)$$

The initial value of the STA is:

$$\text{STA}(\frac{S}{2}) = \frac{1}{S} \sum_{S=0}^{S-1} |x(S)|$$

where:  $x(n)$ : time series

$S$ : the number of samples in the STA window

$L$ : the effective number of samples in the LTA window.

The typical STA length is one second (1.5 seconds for the large array NOA), and 60 seconds for the LTA length.

The STA/LTA threshold (SNR) is specified in the associated beam recipe. When the SNR threshold is exceeded, there is a potential detection. When the SNR thresholds are exceeded for many beams at nearly the same time, the beam with the largest SNR is identified as the best beam. This beam and related parameters are saved for subsequent station processing. An example of identifying the best beam is shown in Fig. 15.8.

### **Onset time refinement**

Once a detection is declared, the trigger time is refined using the Akaike Information Criteria (AIC) (Akaike, 1974). The AIC is applied with a signal window of four seconds with a three second lead time, and a noise window of three seconds which starts six seconds prior to the initial trigger time. The maximum adjustment time is up to two seconds compared to the initial trigger time. The onset time picking error is constrained in the range from 0.685 s to 1.72 s for automatic processing and from 0.12 s to 1.07 s for interactive processing.

For arrays, the AIC is applied twice, i.e., once for the detecting beam after the trigger time is declared, and again for the f-k beam after f-k analysis is performed.

**Fig. 15.8** The best beam for this detection at GERES is the beam with the highest SNR. Top three panels show three beams of GERES, while bottom panels show the SNR traces for these three beams. The beam named GE\_027 has an SNR of 7.5, which is the highest.

***Measure amplitude and period and determine magnitudes mb, Ms and ML***

There are two amplitude types measured by DFX during seismic station processing (Tab. 15.7) which are used for calculating magnitude values. The A5/2 amplitude type is used for calculating the IDC mb magnitude during automatic processing, while the SBSNR amplitude is used to calculate the ML magnitude. After interactive review, the IDC mb magnitude is calculated using A5/2 amplitude type measured from the origin beam.

**Tab. 15.7** Amplitudes computed by DFX during station processing.

| Amp Type | Beam Type  | Filter Band  | Time Window       | Magnitude |
|----------|------------|--------------|-------------------|-----------|
| A5/2     | Coherent   | 0.8 – 4.5 Hz | 6.0 (0.5 + 5.5) s | mb        |
| SBSNR    | Incoherent | 2.0 – 4.0 Hz | 4.0 s             | ML        |

The A5/2 amplitude used for IDC mb magnitude is measured as half the maximum peak-to-trough (or trough-to-peak) amplitude on the vertical channel at three component stations using the fixed filter band 0.8 – 4.5 Hz, while at array stations the A5/2 amplitude is measured on the f-k beam using all vertical sensors at the array using the same filter band and the azimuth and slowness based on the origin for which the mb magnitude is being calculated. The time window used for finding the maximum amplitude is 0.5 s before the first P onset and 5.5 s after the first P onset. Thus, the name A5/2 refers to half peak-to-peak amplitude in a 6 second time window. The period of the A5/2 measurement is based on the three half periods

around the observed maximum amplitude (Fig. 15.9). The A5/2 amplitude measurement is made based on the maximum amplitude found in the time window specified in Tab. 15.7.

**Fig. 15.9** The mb amplitude is measured on filtered vertical channel for arrival at SIV (3-C) (left) and on a coherent f-k beam for all vertical channels at GERES (array) (right). The final period is based on the three half periods between the two green lines. The peak-to-trough amplitude is measured between the interpolated peaks indicated by red lines in the diagrams above.

In contrast to standard mb, which is calculated by calibrating the measured P-wave amplitude, depending on epicentral distance  $\Delta$  and source depth  $h$ , with the Gutenberg and Richter (1956)  $Q(\Delta, h)$  values (see Fig. 1a in DS 3.1), the IDC amplitudes A5/2 are calibrated with the Veith and Clawson (1972) calibration function for 1 Hz vertical component P-waves, which is given for peak-to-trough amplitudes (see Figure 2 in DS 3.1).

The specifics of the IDC measurement procedure for mb has been optimally tuned to the mandate of the CTBTO. This is to assure, amongst others, the best possible detection of and discrimination between underground nuclear explosions (UNE) and natural earthquakes. It should be noted, however, that on average mb(IDC) values are systematically too small for stronger earthquakes when comparing mb(IDC) with mb resulting from NEIC or the new IASPEI (2005 and 2011) standard procedure for mb (Bormann et al., 2007 and 2009). These difference grows with magnitude. While it is negligible for mb (NEIC) < 4 it amounts already to almost -0.5 magnitude units for events with mb(NEIC) between 5.0 and 5.9. For the great 2004 Mw9.3 Sumatra-Andaman earthquake it even reached extreme values between -1.5 and -1.8 m.u., respectively (mb(IDC) = 5.7, mb(NEIC) = 7.2 and mb(IASPEI 2005) = 7.5). The reasons for the more pronounced magnitude saturation of mb(IDC) are discussed in detail in Chapter 3 as well as in Bormann et al. (2007) e.g., the filter band and length of the time window used for calculating amplitude and period.

The SBSNR amplitude for three component stations is measured on the vertical channel using the filter band 2.0 – 4.0 Hz, while at array stations the SBSNR amplitude is measured on a beam using all vertical channels with no steering with the same filter band. No period is measured for the SBSNR amplitude (as for classical ML measurements; see Chapter 3, Section 3.2.4), and the amplitude is calculated as:

$$amp = \sqrt{(MAX(STA))^2 - LTA^2}. \quad (15.1)$$

In contrast to amplitude measurement for mb, based on the maximum P-wave amplitude within the first 5.5 seconds after the first onset of P, the largest short-term-average MAX(STA) is taken over the whole (2-4Hz)-filtered wave train of the considered local event. The SBSNR amplitudes are measured in the distance range  $2^\circ < \Delta < 20^\circ$  and when the difference between estimated depth - depth error is  $< 40$  km.

The attenuation correction for ML is calculated from the formula:

$$a + b * r + c * \log_{10}(r) \quad (15.2)$$

where  $r$  is the epicentral distance (in km) and the coefficients  $a$ ,  $b$ ,  $c$  have been tailored for each station that contributes to the REB to maximize agreement between ML and mb. Each station has its own  $a$ ,  $b$ , and  $c$  values, and the values of these coefficients may change from time to time as part of tuning work to make more consistent magnitudes. The REB ML magnitude is obtained from:

$$ML = \log_{10}(amp/per) + a + b * r + c * \log_{10}(r) \quad (15.3)$$

where  $amp$  is the short-term average amplitude as it appears in the REB in nm (0-peak). It has been transformed from a short-term average value, corrected for long-term noise and measured in a 2-4 Hz bandpass. The period  $per$  in the formula above is always 1/3 sec (0.33 in the REB) for ML, as the amplitude is measured from a bandpass filtered channel (between 2-4 Hz) with a center frequency of 3 Hz. Note that for stations with instrument calibration periods different from 1 sec, the instrument calibration period will enter the formula.

Thus, the IDC ML, based on rms amplitudes being measured on a narrow-band filtered vertical component trace and on coefficients in the ML formula being deliberately tailored to assure best possible agreement between local ML and teleseismic mb, differs from the IASPEI standard ML as outlined in Chapter 3, section 3.2.7.

As mentioned in 15.1.2, the most effective technique used at the IDC for discriminating between natural earthquakes and underground nuclear explosions is the mb/Ms screening criterion. Therefore, additionally to the two body-wave magnitudes, the IDC determines for individual stations also the surface-wave magnitude  $Ms(sta)$ . It is based, as the classical NEIC and now standard  $Ms(20)$  procedure on reading the maximum vertical component surface-wave amplitude at periods between 18 s and 22 s. However, the IDC  $Ms$  values are not calibrated with the IASPEI standard Prague-Moscow calibration formula for surface-wave amplitude readings, but rather with the modified formula (18) in Rezapour and Pearce (1998). The latter avoids distance-dependent biases in  $Ms$  when applying the IASPEI standard formula to exclusively  $20 \pm 2$  s surface waves readings. The reason for these distance-dependent biases in  $Ms_{20}$  are that the IASPEI standard formula used for calibration was derived on the basis of  $(A/T)$  max readings that were not restricted to periods around 20 s but allowing for periods in a much wider range between 2 s and  $< 30$  s (see Vanek et al., 1962; Karnik et al., 1962). Indeed, observations of surface-wave  $(A/T)$  max from globally distributed earthquakes confirm that for earthquakes with magnitudes  $< 7$  and/or recorded at distances  $< 50^\circ$   $(A/T)$  max is measured mostly at periods well below 18 s, down to about 3 s (see Bormann et al., 2009). The  $Ms$  formula used at the IDC reads:

$$Ms(sta) = \log_{10}(amp/per)_{max} + B(\Delta) \quad (15.4)$$

where  $M_s(\text{sta})$  is the  $M_s$  Magnitude for a given station,  $amp$  and  $per$  are from the **amplitude** table ( $amp\text{type} = \text{ALR}/2$ , or  $\text{ANL}/2$ ).  $\text{ALR}/2$  identifies Rayleigh wave signal measurements, and  $\text{ANL}/2$  identifies noise measurements.  $amp/per$  is the maximum amplitude/period ratio within the allowed period range of 18 to 22 s (Stevens and McLaughlin, 2000).  $B(\Delta)$  is identical with the Rezapour and Pearce (1998) calibration function (which is a scaled inverse attenuation formula) for 20 s surface waves. When  $amp$  is measured in nm instead of  $\mu\text{m}$ , then this calibration function reads:

$$B(\Delta) = 1/3 \log_{10}(\Delta) + 1/2 \log_{10}(\sin \Delta) + 0.0046\Delta + 2.370, \quad (15.5)$$

where the term 0.0046 is  $\gamma$  times  $\log_{10}(e)$  ( $= 0.4343$ ), and  $\gamma$ , the attenuation coefficient.  $\gamma$  was determined empirically by Rezapour and Pearce (1998) to be 0.0105 using a very large data set.

### **Estimate azimuth and slowness**

Azimuth and slowness are measured in DFX using different techniques for three component stations (polarization analysis), arrays (f-k analysis), and for the large array (beampacking technique) as shown in Tab. 15.8.

**Tab. 15.8** Azimuth and slowness estimation methods for different station types. The filter band used for f-k analysis at arrays is dependent on the band of the best beam.

| Station type | Method       | Time Window     | Filter band  | Channel    |
|--------------|--------------|-----------------|--------------|------------|
| 3-C          | polarization | 5.5 sec         | 1.0 – 4.0 Hz | Z/N/E      |
| Array        | f-k analysis | 3.15 – 10.8 sec | ~beam*       | Z channels |
| Larray       | beampacking  | 6.0 sec         | 1.2 – 3.2 Hz | Z channels |

\*the filter band depends on the band of the best beam, i.e., the beam with the highest SNR

In polarization analysis for three component stations, polarization analysis is done over a series of overlapping windows near the detection. In each of the overlapping windows a covariance matrix is estimated for the three components of motion and then the eigenvalues ( $\lambda_1, \lambda_2, \lambda_3$ ), and eigenvectors ( $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3$ ) are solved for the covariance matrix. The signal rectilinearity is a measure of the linearity of the particle motion, and is calculated as:

$$rect = 1 - \frac{\lambda_3 + \lambda_2}{2\lambda_1} \quad (15.6)$$

In the overlapping window with the maximum rectilinearity for the short-period filtered P wave the incident angle  $inang$  is estimated as:

$$inang = \frac{\arccos(|u_{11}|)}{90} \quad (15.7)$$

where  $u_{11}$  is the direction cosine of the eigenvector  $\mathbf{u}_1$  associated with the largest eigenvalue.

The observed azimuth,  $seazp$ , of the signal (assuming that the signal is a P-phase) is the azimuth of the eigenvector ( $\mathbf{u}_1$ ) associated with the smallest eigenvalue:

$$seazp = \text{atan2}\left(\frac{u_{13}}{u_{12}}\right) \quad (15.8)$$

The final slowness  $s$  during polarization analysis is calculated as:

$$slowness = polar\_alpha \cdot \sin\left(\frac{inang}{2}\right) \quad (15.9)$$

where  $polar\_alpha = A/(2 \cdot B^2)$ , and  $A = P$ -wave velocity at the station site (km/sec), and  $B = S$ -wave velocity at the station site.

In f-k analysis for seismic arrays, spectra are computed from the vertical channels in a station-dependent time window. For each slowness vector, the f-k power spectrum is calculated as:

$$P(s_n, s_e) = \frac{\sum_{f=f_1}^{f_2} \left| \sum_{i=1}^J F_i(f) \cdot e^{2\pi\sqrt{-1}f(s_n \cdot dnorth + s_e \cdot deast)} \right|^2}{J \cdot \sum_{f=f_1}^{f_2} \left\{ \sum_{i=1}^J (F(i))^2 \right\}} \quad (15.10)$$

where  $deast_i$  and  $dnorth_i$  are the east-west and north-south coordinates, respectively, of the  $i$ th sensor array element relative to the reference station.

The slowness vector with the maximum f-k power is selected for estimating the azimuth and slowness values.

The beampacking technique, also called time domain f-k analysis is used for estimating azimuth and slowness for the large array NOA. This scheme is based on beamforming over a predefined grid of slowness points and measuring the power. The relative power is the signal power of the beam for the peak slowness divided by the average channel power in the same time window.

#### 15.4.2.2 StaPro

StaPro performs the following processing steps:

1. Determine initial wave type – categorize seismic detections as one of four initial wave types: noise (N), teleseismic ( $\Delta > 20^\circ$ ), regional P or regional S ( $\Delta < 20^\circ$ )
2. Group detections – place signals into groups in which each member has similar characteristics suggesting that they were generated by the same event.
3. Assign initial phase name – regional phase identification is done by examining all arrivals from the same group. Phase names for teleseismic data are limited to a simplified phase naming convention used by StaPro.
4. Locate single station events – compute a single-station event location and estimate local magnitude for association groups.

##### **Determine initial wave type**

The initial wave types at seismic arrays are mainly dependent on the velocity estimates from DFX. Tab. 15.9 shows the velocity ranges for determining the initial wave types in StaPro. There are several noise screening functions used at the IDC to recognize noise arrivals.

**Tab. 15.9** Relationship between initial wave types and velocity ranges at seismic arrays.

\*Note that the exact velocity ranges are station dependent.

| Initial wave type | Velocity range*  |
|-------------------|------------------|
| P (teleseismic)   | $\geq 11.0$ km/s |
| P (regional)      | 5.7 – 11.0 km/s  |
| S (regional)      | 2.9 – 5.7 km/s   |
| N(oise)           | $\leq 2.9$ km/s  |

The initial wave types at three component seismic stations are determined using default rules or neural networks. The default rules are shown in Tab. 15.10.

**Tab. 15.10** Default rules for determining initial wave types at 3-C stations. Rect = rectilinearity, hvrat = horizontal to vertical ratio, and freq = central frequency of the detecting channel.

| Signal Type   | Rule                                                                             |
|---------------|----------------------------------------------------------------------------------|
| Teleseismic P | $\text{rect} > 0.7$ and $\text{hvrat} \leq 1.0$ and $\text{freq} < 3$ Hz         |
| Regional P    | $\text{rect} \geq 0.7$ and $\text{hvrat} \leq 1.0$ and $\text{freq} \geq 3.0$ Hz |
| Regional S    | $\text{rect} < 0.7$ or $\text{hvrat} > 1.0$                                      |

Alternatively, neural networks can be applied to determine the initial wave types for three component stations. The neural networks use the signal period, the polarization features, and the context of the given arrival (the relative time difference and the number of arrivals in a window centered on the arrival of interest) as inputs and produce a probability for each of the four classes as output. Three neural networks are used: the first distinguishes between noise and signals, the second one between teleseismic and regional phases, and the last one for regional P and S.

### **Group detections**

Signals are grouped together by StaPro based on the compatibility of the signal type, azimuth, associated azimuth error, amplitude, and relative time difference. The logic flow of the grouping process is shown in Fig. 15.10.

**Fig. 15.10** Logic of the phase grouping algorithm in StaPro, used to group together phases from the same event.

#### ***Assign initial phase name***

The initial phase names are assigned based on the initial wave type and the grouping process. The relationship between initial wave type and initial phase name is shown in Table 11.

**Table 15.11** Initial phase names based on initial wave types.

| Initial Wave Type | Initial Phase Name |
|-------------------|--------------------|
| P (teleseismic)   | P, tx              |
| P (regional)      | Pn, Pg, Px         |
| S                 | Sn, Lg, Rg, Sx     |

#### ***Locate single station events***

Compatible phases which are grouped together can be used to form single station events. During the location process, time, azimuth and slowness values can be defining when locating the event. Each observation which is defining (time, azimuth or slowness) is assigned a certain weight, as shown in Tab. 15.12. Single station events must have a phase weight for 2.6 or more for the single station event to be saved in the automatic bulletin.

**Tab. 15.12** Seismic phase weights used in StaPro for forming a single station event at a primary seismic station.

| Phase type | Station | Time defining | Azimuth defining | Slowness defining |
|------------|---------|---------------|------------------|-------------------|
| Primary    | Array   | 1.0           | 0.5              | 0.5               |
| Secondary  | Array   | 0.7           | 0.5              | 0.5               |
| Primary    | 3-C     | 1.0           | 0.25             | 0.25              |
| Secondary  | 3-C     | 0.7           | 0.25             | 0.25              |

### 15.4.3 Event location

The determination of event hypocentral locations is a core functional element of many automatic and interactive applications within the IDC system. Hypocenters are determined via an iterative non-linear least-squares inversion. A flow chart of this process is shown in Fig 15.11.

**Fig. 15.11** Flow chart of the location process used at the IDC.

#### 15.4.3.1 Input data

Phases used in the location process are known as **defining** phases. A defining phase may have one or more of three attributes that are used in the location process: **time**, **azimuth** and **slowness**. Time-defining phases are the most common.

For seismic data azimuth and slowness defining phases are generally more useful from array stations than from 3-C stations because the standard deviation of the errors tends to be much smaller for array stations.

All infrasonic stations of the IMS are arrays, so for infrasonic data azimuth and slowness information are available for all stations. The hydroacoustic data from the IMS are processed as groups of hydrophones, so azimuth and slowness is available for these data. However, the slowness at hydroacoustic stations is treated as a constant.

### ***Use of time, azimuth, and slowness observations***

Arrival time information is often the best information to use in event determination, but it is often unavailable in sufficient quantity. In such instances, azimuth and slowness information, as obtained from f-k or 3-C analysis, can be added to obtain more reliable hypocenters with smaller uncertainties. In particular, azimuth/slowness estimates are critical when a location is required at a single station.

Pre-determined uncertainty estimates associated with arrival time information are typically better than that of azimuth/slowness information, these latter data can actually prove counterproductive to the goal of accurate event location.

In practice, the IDC analysts exclude azimuth and slowness estimates from seismic data when more than **six defining arrival times of primary stations** are available to the hypocentral location process.

### ***Establishing the initial location***

A reasonable seed (starting) location increases the likelihood of finding the global minimum. The initial locations in preferential order are:

- 1) a previously determined hypocenter;
- 2) a location based on an exhaustive grid search as determined by the GA (Global Association) subsystem;
- 3) an internal “best guess” algorithm built into the location library.

In the rare situation when a best guess seed location must be made, the strategy is to use the combination of arrival time, azimuth, and slowness information. The seed algorithm uses a list of **location scenarios** to find a starting location:

- Use the time defining S–P time at the closest seismic station and the best-determined defining azimuth from a seismic station to compute a seismic epicentral location.
- Use various combinations of defining S–P times and defining P-wave arrival times from seismic stations to compute a seismic epicentral location.
- Use the two best defining azimuths available from two different stations to define two great circles whose intersections are candidates for the seed location. Choose the location that is closest to the two stations.
- Compute a seismic epicentral location by using the best P-wave azimuth (for direction) and slowness (for distance) from a single seismic station.
- Put the epicentral location near the closest station. Use azimuth information, if available.

### ***Predicting travel-time, azimuth and slowness values***

Travel-time, slowness, and azimuth of seismic phases can all be used for locating seismic events. The IASPEI-91 travel time tables contain travel-time parameterized by distance and depth. The modeling error associated with a given phase-dependent travel-time table is also explicitly specified. Travel-time corrections include:

- Ellipticity correction
- Elevation correction
- Source-specific station correction (SSSC)

### ***Source-Specific Station Correction (SSSC)***

Source-specific station corrections to the travel time of a seismic phase attempt to correct for the travel-time effects of lateral heterogeneity. SSSC tables are specified by a two-dimensional parameterization along latitudinal and longitudinal nodes. By introducing SSSC information the phase-dependent modeling errors assumed within the one-dimensional travel-time tables should be reduced.

### ***Predicting seismic slownesses and azimuth values***

The slowness model is based on the derivative of travel time with respect to distance. Azimuth modeling is based on the exact azimuth between the station and the hypothesized event location.

Azimuth and slowness data from seismic stations are most useful for locating small events, especially when their data importances are high. Unfortunately, significant biases that can map into large event mislocations exist within these data. These biases, coupled with relatively large modeling and measurement errors, also produce very large error ellipses. The goal of the slowness-azimuth station corrections (SASC) is to remove these systematic biases from these azimuth-slowness measurements

### ***Slowness-Azimuth Station Corrections (SASC)***

The slowness/azimuth station corrections and related modeling errors are represented on a binned polar slowness/azimuth grid (Bondar, et al, 1999). A constant correction and modeling error is defined over the entire bin. A background correction and modeling error can be defined for those bins without a specified SASC. The background correction is parameterized as a vector slowness correction to adjust for large-scale structural features near the station. In addition, rotational coefficients are specified. These are to be applied to each slowness vector. The total background correction is thus an affine transformation of the slowness vector with a constant component and a rotational component.

### ***Hydroacoustic measurements***

Hydroacoustic stations with hydro-channel groups can be used to estimate azimuth (typically under the assumption of fixed slowness). Travel-times and, if available, azimuths of hydroacoustic phases and knowledge of all possible source locations for those phases (expressed as blockage grids for each hydroacoustic station) are used for locating events detected by hydroacoustic network.

The hydroacoustic travel-time model is complicated by the dynamic nature of the oceans through which the hydroacoustic phases propagate. Unlike the seismic travel-time predictions for which corrections are applied to a standard one-dimensional model, seasonally varying travel-time models are used to predict the propagation times for hydroacoustic phases. One-dimensional models are used only if the seasonal models are unavailable.

Because of the slow propagation velocity in the ocean and spatial and seasonal variations in temperature that induce velocity variations, actual travel times may depart substantially from constant-velocity travel times. To account for these spatio-temporal variations, the system provides for the use of seasonally varying, azimuth, and range-dependent travel-time tables specifically calculated for each hydroacoustic station. The travel times and their modeling uncertainty are specified on a polar grid centered at the station.

### ***Hydroacoustic blockage***

Hydroacoustic phases propagate long distances with limited attenuation in the water column. The phases are converted at the water-land interface of sizable islands or continents, but the converted waves do not propagate efficiently and are effectively blocked by the island or continental mass.

Blockage is modeled for each hydroacoustic station as the maximum distance of propagation along a set of azimuths. The blockage subsystem is not used as an integral part of the location algorithm. Rather, it is invoked directly by several applications (ARS and GA for instance) to check if a path is topographically blocked. ARS is the software used by IDC analysts to review waveform data. The Global Association software is used during automatic processing to associate phases and form events.

### ***Infrasound measurements***

All of the infrasonic stations of the IMS are arrays and thus the data from these stations yield travel-time, azimuth, and slowness values.

Infrasound does not propagate with a constant velocity in a straight line from its source to the receiver. Rather, there appear to be two basic mechanisms for transporting low frequency acoustic energy in the atmosphere. The first is via reflections between the Earth's surface and the Stratosphere at an altitude of around 50 km. The second is via reflections between the Earth's surface and the thermosphere at an altitude of around 120 km. This 'ducting' can be responsible for the horizontal transmission of infrasound over many thousands of kilometers.

Currently at the IDC the initial infrasonic phase is used during location, and is designated with the phase name I. The propagation model shown in Tab. 15.13 is used, and a large modeling error is attributed to that value. Travel times are specified as an extension of the IASPEI-91 travel time curves.

**Tab. 15.13** Infrasound wave propagation model used at the IDC.

| <b>Infrasound wave type</b>            | <b>Distance Range (deg)</b> | <b>Velocity (km/s)</b> |
|----------------------------------------|-----------------------------|------------------------|
| Direct arrival and Tropospheric regime | 0 to 1.2                    | 0.330                  |
| Stratospheric/Thermospheric regime     | 1.2 to 20                   | 0.295                  |
| Stratospheric regime                   | 20 - 60                     | 0.303                  |

### 15.4.3.2 Nonlinear least-squares inversion

Hypocentral inversion or event location is performed as a nonlinear least-squares inversion of travel time, azimuth and slowness measurements from stations at local, regional and teleseismic distances.

Input data:  $N$  observations (travel times, slownesses, azimuths);

initial guess of event location and origin time ( $lat_{org}$ ,  $lon_{org}$ ,  $depth_{org}$ ,  $t_{org}$ ).

Goal: Minimize the sum of squares of  $N$  non-linear functions (weighted residuals) that depend on a set of parameters ( $lat_{org}$ ,  $lon_{org}$ ,  $depth_{org}$ ,  $t_{org}$ ).

$$\begin{bmatrix} res_1^{tt}/\sigma_1^{tt} = t_1^{obs} - t_{org} - t_1^{pred}(lat_{org}, lon_{org}, depth_{org}, lat_{sta1}, lon_{sta1}) \\ res_1^{sl}/\sigma_1^{sl} = sl_1^{obs} - sl_1^{pred}(lat_{org}, lon_{org}, depth_{org}, lat_{sta1}, lon_{sta1}) \\ res_1^{az}/\sigma_1^{az} = az_1^{obs} - az_1^{pred}(lat_{org}, lon_{org}, lat_{sta1}, lon_{sta1}) \\ res_2^{tt}/\sigma_2^{tt} = t_2^{obs} - t_{org} - t_2^{pred}(lat_{org}, lon_{org}, depth_{org}, lat_{sta2}, lon_{sta2}) \\ \dots \\ res_N^{tt}/\sigma_N^{tt} = t_N^{obs} - t_{org} - t_N^{pred}(lat_{org}, lon_{org}, depth_{org}, lat_{staN}, lon_{staN}) \end{bmatrix}$$

where  $\sigma = \sqrt{\sigma_{model\_err}^2 + \sigma_{measure\_err}^2}$

### 15.4.3.3 Evaluating the solution

Events are located through an iterative procedure. The procedure is continued, while stable, until convergence is achieved, divergence is recognized, or the maximum number of iterations has been exceeded.

#### **Stability**

If the location adjustment at a given iteration is extremely large, then the revised location may be suspect; the stability of the solution is questionable. If the adjustment has been identified as being very large, then the first step is to scale down the adjustment. In the early iterations this means not permitting the location to move more than 3000 km in a single step. For latter iterations this step is reduced to 1500 km.

#### **Divergence tests**

Local divergence is associated with a single iteration where the location seems to be getting worse because the current adjustment vector is larger than that encountered during the previous iteration. Global divergence is established when local divergence of sufficient magnitude is identified over two consecutive iterations. A single local divergent iteration is harmless and permits the iterative process to continue. If two consecutive locally divergent steps are identified, the last more than 10% worse than that two iterations prior, then global divergence is declared, and the iterative location process is terminated with an appropriate error message.

### ***Convergence tests***

If the total spatial adjustment vector in all dimensions is less than 0.5 km coupled with an origin time change of less than 0.5 s, then the solution has converged.

### ***Maximum iteration test***

If convergence has not been achieved, iteration is terminated when the maximum number of iterations is reached. The maximum number of iterations for location is set to 60 for analyst review. A minimum of four iterations are always performed.

The iteration number is also used to control the conditions of the inversion. The depth element of hypocentral parameters is constrained (fixed) during the first two iterations.

### ***Updating hypocenters***

After all of the stability and convergence tests have been completed the hypocenter is updated based on the newly-determined adjustment solution vector. When convergence or divergence has been declared, the prediction process has to be invoked one last time so the data residuals and network statistical measures coincide with the most recently adjusted hypocenter.

### ***Estimating errors***

Estimating errors includes calculating the model covariance matrix, data resolution matrix, the resultant 90th percentile error ellipse, depth error, and origin time error.

## **15.4.4 Event definition criteria**

The IMS network records a variety of signals from events throughout the world. A criterion is applied in order to decide which events to include in the automatic and reviewed bulletins produced by the IDC. Considering the mission of the organization, to look for evidence of potential Treaty violations, the concept of the event definition criteria was introduced.

Each event recorded by the network is composed of defining phases used in the location process. Each of these defining phases is assigned a weight, and the sum of these weights is the weight of the event (Tab. 15.14). Note that defining phases at auxiliary seismic stations do not contribute to the weight of an event, but auxiliary seismic stations are used to refine the event solution. Events must have a weight of 3.55 or above to appear in the SEL1, SEL2, or SEL3 bulletins, and an event must have a weight of 4.6 or above to appear in the REB (reviewed event bulletin). This essentially means that an event must be observed by at least two primary stations to appear in the automatic bulletins (SEL1, SEL2, SEL3), and must be observed by at least three primary stations to appear in the REB. Primary stations in this case refer to primary seismic stations, hydroacoustic stations, and infrasound stations.

**Tab. 15.14** Phase weights used for event definition criteria. A primary seismic type phase is the first P-type phase (from the list P, Pn, Pg, or PKP) and the secondary seismic type phases are all subsequent defining phases.

| Phase Type        | Station Type          | Arrival Time | Azimuth | Slowness |
|-------------------|-----------------------|--------------|---------|----------|
| Primary seismic   | Primary seismic array | 1.0          | 0.4     | 0.4      |
| Secondary seismic | Primary seismic array | 0.7          | 0.4     | 0.4      |
| Primary seismic   | Primary seismic 3-C   | 1.0          | 0.2     | 0.2      |
| Secondary seismic | Primary seismic 3-C   | 0.7          | 0.0     | 0.0      |
| H                 | Hydroacoustic         | 1.2          | 0.6     | 0.0      |
| I                 | Infrasonic            | 0.8          | 1.0     | 0.0      |

## 15.5 Data availability

The data from the IMS network and the bulletins from the IDC are available to authorized users in close to real time. Each country that has signed the CTBT may designate a National Data Centre (NDC). Staff at the NDC and other institutes may be designated as authorized users.

Additionally, the Review Event Bulletin (REB) is also provided to the International Seismologic Centre (ISC), who includes the REB as one of their contributed bulletins. The ISC bulletin is freely available from <http://www.isc.org>.

There is also a new CTBTO initiative known as the Virtual Data Exploitation Centre (VDEC), which aims to make data and products more widely available to the broader scientific community. More information about this project can be obtained by sending your inquiry to the email address [vdec@ctbto.org](mailto:vdec@ctbto.org).

Moreover, many products of the former Prototype International Data Center (PIDC) are available at the Defense Threat Reduction Agency (DTRA; <http://www.dtra.mil/Home.aspx>) Verification Data Base (<http://www.rdss.info>). This website permits access to and data retrieval from an extensive (>18 Terabytes) archive of hydroacoustic, infrasound and seismic waveform data covering 1994-present, and access to an archive of event bulletins from the PIDC (1995-Sept. 2003) as well as of the IDC with several years delay (as of 2011 IDC data 2000-2004). On this website one finds data availability statistics and infrasound station metadata from stations that are part of the IMS as well as from a few selected non-IMS sites. A research data base provides access also to waveforms, signal measurements and source information drawn from a wide variety of official and unofficial sources for nuclear explosions, GT locations and infrasound events. When available, also waveform data from these events can be retrieved via AutoDRM.

## Introduction

In Chapters 2 and 11 the complexity of seismic waveforms is explained in detail. Much experience is needed to identify the seismic phases correctly and to pick onset times accurately and consistently. The majority of our current knowledge of the Earth's seismicity

is based on manual picking of onset times. In addition, manual picks have been used for the investigation of the structure of the Earth. However, for early warning purposes and for the processing of large data sets automatic picking is needed. Because of the variability of seismic waveforms, the occurrence of different seismic phases and the presence of noise, automatic picking remains still a challenge. Yet, in the light of the rapidly growing amount of digital waveform data produced by permanent and temporary networks, the issue of automatic event detection and phase picking becomes more and more important. Accordingly, the number of published algorithms has increased significantly during the past years. This makes it difficult for potential users to keep track of the different approaches and developments, even more, since most algorithms have been developed for a certain data set or a particular problem, such as early warning, real-time location, tomography, etc. Accordingly, only few algorithms were widely established in the community of observational seismology. Generalization of essential principles and criteria as well as large-scale comparative benchmark tests of different existing algorithms are still extremely rare. This makes it difficult for interested developers to choose the most appropriate approach, especially when aiming at multi-task high-quality performance, and for users to select the most suitable algorithms among the many available techniques for their specific problem. With this Chapter we intend, therefore, to provide a broader introduction into the problem of automated event detection and phase identification, to outline the underlying theory and methodological approaches, to illustrate results produced by different procedures, to assess the performance of available algorithms, to sketch the likely development in the near future and to highlight essential practical considerations for the application of automatic picking procedures.

### **16.1.1 General Remarks**

With the advent of digital real-time acquisition systems automated real-time event detection and location became feasible. Beginning around 1975, High Gain Long Period (HGLP) stations, including both digital and optical recordings, were deployed by the Seismic Research Observatories (SRO). WWSSN-stations were digitally upgraded (DWWSN), which constitute the Global Digital Seismic Network (GDSN) (e.g. Lay and Wallace, 1995). At the same time, rapid advances in computer technology enabled sophisticated analysis of increasing amount of seismic data. Nowadays, several digital, global seismic networks are in operation, monitoring continuously the global seismicity and providing rapid locations of earthquakes within minutes. Automated rapid and robust detection and location of earthquakes using real-time data of regional and global networks is essential for earthquake early warning systems. Usually, only automated first onset picks are used. A large number of automated P picks is required to ensure the robustness of the automated location. Fast automated locations are replaced after some time by more accurate manual locations that use also picks of later phases.

The need for automatic picking algorithms arises also from the increasing amount of digital data sets produced by modern passive seismic networks. Even local, temporary networks, as needed for reservoir characterization during stimulation experiments at enhanced geothermal systems (EGS) or hydrocarbon reservoirs, monitor ten-thousands of seismic events at high sampling rates. For tomographic studies, which usually require data merged from several seismological networks, highly accurate and consistent phase arrival times are needed. Automated post-processing algorithms have been developed to determine and select consistently high-quality picks for tomographic purposes whose quality might be even better than those of manual phase readings. The examples given above are typical applications of

automated seismic event detection and automated arrival time estimation. Automated processing schemes show the following potentials:

- fast and near-real time data processing;
- consistent arrival time estimation;
- processing of large data sets;
- if implemented, consistent onset quality estimation and phase identification.

The algorithms to choose depend on the specific application. Of course, the more precise and powerful the automated onset determination is, the more computationally expensive the applied algorithms are. For rapid earthquake location estimates or phase identification simple STA/LTA detections may be sufficient. E.g., Earle and Shearer (1994) use STA/LTA ratios taken from a smoothed envelope function, determined using a Hilbert transformation of the seismogram, to detect first and later arrivals. These algorithms are usually referred to as *phase detectors* in contrast to more accurate arrival time estimation algorithms, which are usually referred to as *phase pickers* (Baer and Kradolfer, 1987) and needed for precise location of earthquakes or tomographic studies. There is a considerable amount of automated picking algorithms available. Usually, these algorithms are optimized for certain requirements. Comparative studies and calibration tests are not yet common practice. While the STA/LTA detector is described in detail in Information Sheet IS 8.1, we here review the most widespread automatic picking algorithms and analyze their properties. An introduction to automatic phase identification is given.

Also the accuracy of manual readings is limited due to sampling rate, noise, or the occurrence of emergent onsets. These uncertainties must be added to the theoretical time resolution of modern, GPS-based broadband seismic networks, which allow precisions of P-onset readings within 0.2 s (e.g.; iP phases in teleseismic events; Leonard, 2000). Further problems are the inconsistency of manual picks, phase misidentification and incomplete documentation of applied filters. Douglas et al. (1997) compared P-wave readings of explosion and earthquake recordings. He showed that errors of manual picks are in the order of 0.1 seconds for explosions and about 0.5 seconds for teleseismic earthquakes with a magnitude range from 4.6 to 6.1. Using data of the Montana Bureau of Mines and Geology (MBMG) network, Zeiler and Velasco (2009) investigated manual picks of local and regional first arrivals. They found that the pick error is 0.1 seconds for phase measurements with high signal-to-noise ratios. Furthermore, the manual readings were biased towards late picks. Interestingly, in a second study using data collected by the International Seismological Center (ISC), they found that picks by different institutions may be inconsistent though individual institutions pick consistently. The standard deviation from the average arrival time determined from readings of several institutions for one single event varied between 0.2-0.6 seconds. For location purposes, the pick uncertainty should be significantly lower than the RMS-travel time residuals due to wave propagation effects not accounted for. From this point of view it is obvious that automatic phase picking has the potential to improve the consistency of arrival time estimations if it is supplemented by thorough quality estimations.

In the entire processing scheme from automated event detection to automated event location, usually a phase detector is applied to all available recordings first. Then the consistency of these detections is checked in order to detect an event. After a seismic event has been recognized, the more precise phase picker is applied to the time series to obtain arrival time estimations for a robust earthquake location. Following this basic processing scheme, section

16.2 gives an introduction to event detection based on phase detectors applied to a network of stations. In section 16.3 the following established P-phase picking algorithms are described: (1) the Allen-picker, (2) the Baer- and Kradolfer-picker, (3) picking based on Higher Order Statistics (HOS) and (4) Autoregressive-Akaike-Information-Criterion-picker (AR-AIC). Picking of later arrivals is briefly introduced in section 16.4. Automated algorithms for quality estimation and phase identification as well as outlier detection are discussed in section 16.5. Practical considerations on automatic picking, pre-processing and calibration are given in section 16.6.

The following section gives a brief overview on existing phase detection and picking algorithms. As the algorithms are presented in chronological order, this sub-section serves as a short historical overview on the development of automated picking algorithms.

### 16.1.2 Historical overview

One of the first mathematically based signal detectors was the one proposed by Freiburger (1963), who applied an approximate comparison of spectral densities for the detection of Gaussian signals in Gaussian noise. This method is suitable for detecting signals rather than measuring signal onset times. Stewart (1977) developed an automated procedure for P-phase detection, P-phase processing and coda processing for local seismic event analysis in central California. Using three moving windows for computing "moving-time noise averages" from the original seismic trace and its first difference, it is tested, whether the seismic station is operating within acceptable limits of noise or not. A P phase is detected, if the threshold exceeds 2.9 times the noise level. Goforth and Herrin (1981) developed an automatic seismic signal detector based on the Walsh transform, which is quite similar to the Fourier transform but computationally less expensive. Michael et al. (1982) used this approach to develop a real-time event detection and recording system for the MIT Seismic Network. Joswig (1987) proposed a pattern recognition technique using characteristic event features in spectrograms. However, the precision of these algorithms is limited.

A fundamental step towards automatic phase-onset determination was the algorithm proposed by Rex V. Allen (1978, 1982). He introduced the concept of the characteristic function (CF), resulting from non-linear transformations of the seismic trace to which a picker is applied. Allen's CF is based on short-term-average to long-term-average ratios (STA/LTA) calculated from an approximative squared envelope function of the seismogram. This picking algorithm is still frequently applied and used for automatic picking e.g. by the USGS Earthworm system (Johnson et al., 1995). Baer and Kradolfer (1987) developed an automatic phase picker by slightly changing Allen's envelope function and incorporating a dynamic signal threshold. This algorithm marks a milestone in automated phase picking and is still frequently used, e.g. in the Programmable Interactive Toolbox for Seismological Analysis (PITSA, Scherbaum and Johnson, 1992) and MannekenPix (Aldersons, 2004). Furthermore, in combination with a sophisticated quality assessment this algorithm yields high-quality onset times useful for tomographic studies (e.g. Di Stefano et al., 2006, Diehl et al., 2009b). Higher order statistics are proposed e.g. by Saragiotis et al. (2002) and Küperkoch et al. (2010) where skewness and kurtosis are calculated in sliding windows generating the CF. These algorithms provide very reliable P-arrival time estimates.

Beside these time and frequency domain approaches, model oriented algorithms became quite common, too. Autoregressive (AR) techniques are widely used. Based on the Akaike

Information Criterion (AIC), Takanami and Kitagawa (1988) developed a procedure for the fitting of a locally stationary autoregressive model to seismograms. They implemented this procedure in an on-line system and called it FUNIMAR (fast univariate case of minimum AIC method of AR model fitting). Leonard and Kennett (1999) propose an autoregressive method that detects increases in the AR-model order due to the higher complexity of signals compared to preceding noise. The standard autoregressive two-model Akaike Information Criterion (AR-AIC, e.g. Sleeman and van Eck, 1999) estimates the AR coefficients from predefined noise and signal windows.

Gentili and Michelini (2006) propose an artificial neural network approach for P- and S-phase onset time determination, called innovative model of neural network (IUANT2). They use variance, skewness, kurtosis and a combination of skewness and kurtosis and their time derivatives.

Many automatic phase-detection algorithms incorporate several approaches, using the different advantages of the applied methods (e.g. Zhang et al., 2003; Bai and Kennett, 2000). Nippres et al. (2010) applied STA/LTA picker, higher order statistics (Saragiotis et al. 2002) and damped predominant period  $T^{pd}$  (Hildyard et al., 2008; Hildyard and Rietbrock, 2010) picker to ANCORP data to estimate P- as well as S-arrival times.

Algorithms for the estimation of relative travel times instead of absolute ones have been proposed in order to improve the picking accuracy. Examples are multi-station and array approaches using cross-correlation methods (VanDecar and Crosson, 1990) or adaptive stacking techniques (e.g. Rawlinson and Kennett, 2004; Rowe et al., 2002). These methods require high waveform coherence at neighboring stations and high signal to noise ratios as is observed for example in the case of low-pass filtered teleseismic waveforms.

## 16.2 Phase and event detection

In order to obtain first rough P-phase arrival time estimates, a single-station detector - e.g. a simple STA/LTA trigger (see IS 8.1) - is applied to all available continuous data streams of a seismic network. An analog or digital version of this detector might be implemented directly at the stations. Then data in a short time interval following the detection are transmitted to the data center for further analysis. Nowadays, usually continuous data streams are transferred to the data centers where a phase detector is applied to the incoming real-time data. A theoretical justification for the STA/LTA trigger based on the logarithm of the likelihood ratio can be found in Basseville and Nikiforov (1993).

Event detectors are configured so that the number of false detections is minimized. On the other hand the detector has to be sensitive enough in order to detect also smaller events. Therefore, any phase detector yields a considerable number of false detections and not all P phases are detected. Hence, the consistency of the detections at different stations has to be checked before the detection of an event is declared. For local seismic networks it is sufficient that within a short time interval of a few seconds P phases are detected at a certain number of stations. The time of the phase detection  $\hat{T}_i$  at station  $i$  is interpreted as an estimation of the P- phase arrival time, which is, of course, afflicted with an error  $\varepsilon_i$ .  $\hat{T}_i$  may be written as:

$$\hat{T}_i = T_0 + t_i + \varepsilon_i,$$

where  $T_0$  is the source time and  $t_i$  is the travel time of a P wave to station  $i$ . The coincidence trigger detects an event, if for any combination of a minimum number of stations (typically three or four) the condition

$$|\hat{T}_i - \hat{T}_j| \leq \varepsilon$$

is met.  $\varepsilon$  is the maximum allowed difference between trigger times at neighboring stations. This coincidence trigger works satisfying for local networks, where the number of stations and the aperture of the network are not large. For regional and global networks this simple event detection algorithm has to be modified. Such a modified algorithm may be formulated as a grid search procedure. At every knot of a 3D grid a hypothetical hypocenter is assumed. The index  $k$  is introduced for a hypothetical hypocenter.  $T_{ki}$  denotes the expected P-phase arrival time at station  $i$ . The expected difference between arrival times at two stations for the assumed hypocenter  $k$  is

$$\Delta T_{kji} = T_{ki} - T_{kj} = t_{ki} - t_{kj},$$

where  $t_{ki}$  is the travel time from the hypocenter  $k$  to station  $i$ , that is in practise calculated using a reasonable background velocity model. The expected travel time difference  $\Delta T_{kji}$  may serve as a condition that an event is detected at the hypothetical hypocenter  $k$ . If for a certain number of detections  $\hat{T}_i$  occuring in the time interval  $[t - \Delta t, t]$  the condition

$$|\hat{T}_i - \hat{T}_j - \Delta T_{kij}| \leq \varepsilon$$

is met, an event at the hypocenter  $k$  is declared. Only trigger times at predefined subsets of stations in the vicinity of the hypocenter  $k$  need to be checked in order to detect an event at hypocenter  $k$ . This algorithm is fast and yields robust preliminary event locations even if the single-station phase detector produces a large number of false detections. This algorithm is implemented i.e. in the Earthworms phase associator “Binder” (Dietz, 2002).

A similar approach is proposed by Le Bras et al. (1994) in the widely used system Global Association (GA), where explicitly identified phases are assigned to synthetic earthquakes in overlapping circular grid cells with a complete global coverage. The performance of this algorithm relies on the correct phase identification, which is based on a combination of slowness and f-k analysis, polarization analysis, and frequency content.

Waveform correlation is used to identify seismic events. For finite-length time series from STA/LTA-triggered systems, Withers et al. (1998) propose the Local Waveform Correlation Event Detection System (LWCEDS). From observed waveforms envelopes are calculated using STA/LTA energy ratios and correlated with pre-calculated travel-time curves, which are transformed into processed time series by applying an envelope function to the arrival times for each distance bin. A single value for each station is summed, and the result is normalized by the number of stations, giving the final correlation value. After the summation over all given grid points and time intervals, respectively, the maximum sum is determined and an event is declared, if this maximum sum exceeds a certain threshold.

A grid search algorithm, which works without onset time detections, is proposed by Kao and Shan (2004). Within this Source-Scanning Algorithm (SSA) a brightness function is calculated by summing the absolute, normalized amplitudes observed at all stations at their predicted arrival times, i.e.

$$br(k, T) = \frac{1}{N} \sum_{i=1}^N |u_i(T + t_{ki})|$$

where  $u_i$  is the normalized seismogram at station  $i$ ,  $t_{ki}$  is the predicted traveltime from point  $k$  to station  $i$  of a particular phase with the largest observed amplitude (on regional scale S phase). The brightness is calculated of a point  $k$  at a specific time  $T$  and varies from 0 to 1. The brightness becomes 1 if all the largest amplitudes originate from a source at point  $k$  and time  $T$ . The spatial and temporal distribution of sources is identified by a systematic search throughout the model space and time for the maximum brightness. For each source, this scanning algorithm results into a center of maximum brightness. Waveform based association algorithms may also be applied to the detection and location of tremors. The SSA algorithm was successfully applied to locate non-volcanic tremors in the northern Cascadia subduction zone (Kao and Shan, 2004).

In the case of earthquake data, the event detection is usually followed by a more precise automatic picking of P and optionally also S phases that allow to improve the event location.

## 16.3 Automated P-onset determination

After an event has been identified, an interval of the time series containing the seismic signal is usually cut out for detailed processing. For a precise event location, a picking algorithm is applied to the data to estimate P- and S-phase arrival times, respectively. In this section we review the most frequently applied and wide spread P-picking algorithms. We describe the algorithms and show applications to synthetic as well as to real examples in order to demonstrate properties and the performance of the picking algorithms. All pickers are applied to the same local, regional and teleseismic event example waveforms for reasons of comparison. Furthermore, the behaviour of the corresponding CFs are tested on synthetic data with instantaneous changes in amplitude, frequency, and phase, respectively, as the arrival of a body wave may be indicated by one or several of those changes. The synthetic examples are designed to investigate the properties of the CF rather than to simulate a P-wave arrival.

### 16.3.1 The Allen picker

Allen (1978, 1982) introduced the concept of *characteristic function* CF, where the "character" of the seismic trace is specified. The CF is obtained by one or several non-linear transformations of the seismogram and should increase abruptly at the arrival time of a seismic wave. In addition to the calculation of the CF the next steps of a picking algorithm are the estimation of the arrival time from the CF and the quality estimation.

Let  $x_i$  be the time series under investigation with first difference  $\Delta$ , Allen defined the following envelope function  $E(t)$ :

$$E_i = x_i^2 + C_i \cdot \dot{x}_i^2, \quad (16.1)$$

where  $C_i$  is a weighting constant with

$$C_i = \frac{\sum_{j=1}^i |x_j|}{\sum_{j=1}^i |x_j - x_{j-1}|} \quad (16.2)$$

to control the relative contributions of amplitude and derivative. For a harmonic  $x_i$ , equation (16.2) reduces approximately to

$$C_i = \frac{1}{f_i dt}, \quad (16.3)$$

where  $f$  is the frequency and  $dt$  the sampling frequency. If  $C_i$  in eq. (16.1) was squared, this envelope function would be an effective, recursive approximation of the squared envelope. That means the envelope function eq. (16.1) represents a fast but rough approximation of the waveform envelope.

In the context of this article, we refer to the definition of the CF by Baer and Kradolfer (1987), who defined the CF as the time series, to which the picker is applied. Note, that Allen (1978) uses the term CF slightly differently. According to his notation the envelope function  $E(t)$  represents the CF, though the picker is applied not to this function but to the STA/LTA ratio calculated using the envelope function. In order to illustrate properties of  $E(t)$  it is calculated for synthetic data with sudden changes in amplitude, frequency, and phase, respectively. From Fig. 16.1 it becomes obvious that only changes in amplitude are detected by Allen's CF.

**Fig. 16. 1** Allen's approximated squared envelope function (blue) for synthetic data (black) with a change in amplitude (top), change in frequency (middle) and change in phase (bottom). envelope function. That means  $E(t)$  is sensitive to sudden changes in amplitude and frequency.

The following sophisticated algorithm is applied to  $E(t)$  in order to obtain an arrival time estimate and to check the reliability of the pick. At first an STA/LTA criterion is used to detect possible arrival times. Then the duration of the signal is considered in order to distinguish between noise and P-wave arrivals and to reduce the number of false alarms. In the following description of the Allen picker we refer to the Fig. 16.2 and 16.3:

A short-term average ( $\alpha$ ) and a long-term average ( $\beta \approx 100 \cdot \alpha[s]$ ) are calculated from the envelope function. If the STA/LTA ratio exceeds the reference level  $\gamma$ , the time is provisionally stored as a pick and the reference level  $\gamma$  is frozen (Fig. 16.2c). The picker now confirms or rejects the provisionally onset time by investigating the amplitudes of the raw seismogram. If low amplitudes (i.e. STA values exceed the continuation level  $\delta$ ) prevail, the picker assumes a short-term increase of noise and rejects the provisionally onset. If higher amplitudes prevail (i.e. STA values above the continuation level  $\delta$ ), the picker assumes a real seismic signal and estimates the length of this signal. To distinguish between short-term increases of noise and the seismic signal, the algorithm searches for the next zero crossing in the seismic trace. Reaching the next zero crossing, the picker starts counting the number  $M$  of observed peaks.  $M$  is incremented by 1 at each zero crossing. Using the number of observed peaks  $M$ , the continuation criterion  $\delta$  is determined by  $\delta = \beta(j) \cdot M$  and a "termination number"  $L = 3 + 3/M$  (Fig. 16.2d,e) is calculated.  $\delta$  and  $L$  are constantly increasing functions and serve as parameters to identify the length of the signal and hence to confirm the provisionally pick. In addition, also small amplitudes are counted: the short-term average  $\alpha$  is compared with the continuation criterion  $\delta$ . If  $\alpha$  exceeds  $\delta$ , a counter  $s$ , which Allen refers to as a "small count counter" and which counts the number of successive zero crossings occurring since  $\alpha$  drops below  $\delta$ , is reset. If  $\alpha$  does not exceed  $\delta$ ,  $s$  is incremented by 1. If  $s$  becomes larger than the termination number  $L$ , the event is supposed to be over, otherwise the processing goes on until  $s > L$ . The length of the time interval for which  $L > s$  serves as an estimate of the signal length (Fig. 16.2e). From Fig. 16.2d,e it is obvious, that the small count counter  $s$  increases significantly steeper than the termination number  $L$  as soon as the short-term average  $\alpha$  remains below the continuation criterion  $\delta$ . If the signal length exceeds a certain threshold  $t_{min}$ , the signal is supposed to be a seismic event, the pick is stored and optional post-processing starts. If the signal length is too short, the pick is removed,  $s$ ,  $L$ ,  $M$  and  $\delta$  are reset and a new reference level  $\gamma$  is calculated.

In order to account for automatic quality and error assessment, Allen introduced a weighting scheme, based on the seismogram and the corresponding CF. The estimated weights of the determined P onsets may serve as input for the location routine HYPOINVERSE (2002, 2003), where weight-0 onsets denote excellent or impulsive (100 % weight), weight-1 very good (75 % weight), weight-2 good (50 % weight) and weight-3 intermediate onsets (25 % weight). Weight-4 picks are not used for location. The information needed are

- $B$ , a measure of the noise level at the detection time;
- $A_0$ , the trace amplitude at the detection time;
- $D$ , the trace first difference at the detection time;
- $A_1, A_2, A_3$ , the first three amplitude peaks.

For a weight-0 P onset ("excellent"), the detection has to meet the following criteria (after Allen, 1978):

1.  $D > \sqrt{B}$ ,
2.  $A_1 > 450$ ,
3.  $A_1/\sqrt{B} > 4$ ,
4.  $A_2 > 6\sqrt{B}$  or  $A_3 > 6$ .

These criteria are successively to be relaxed to obtain lower weights 1,2 and 3.

**Tab. 16.1** Parameters to be adjusted for the Allen picker. The outer right columns represent the values of the parameters used for the example waveforms in Fig. 16.4.

| Parameter | Remark                         | Values                  | Local | Regional | Tele |
|-----------|--------------------------------|-------------------------|-------|----------|------|
| $\alpha$  | short-term-average of CF [s]   | $0.01 < \alpha \leq 10$ | 0.1s  | 0.1s     | 10s  |
| $\beta$   | long-term-average of CF [s]    | $2 < \beta \leq 50$     | 5s    | 5s       | 50s  |
| C3        | weighting of STA values        | $0.2 < C3 \leq 0.8$     | 0.2   | 0.2      | 0.8  |
| C4        | weighting of LTA values        | $0.005 < C4 \leq 0.05$  | 0.005 | 0.005    | 0.05 |
| C5        | $LTA * C5 = \delta$            | $\sim 5$                | 2     | 2        | 3    |
| tmin      | minimum signal length required | 1.5 [s]                 | 3s    | 3s       | 40s  |

Fig. 16.4 shows applications of the Allen picker to waveforms of local, regional and teleseismic events. As shown by e.g. Küperkoch et al. (2010), this picking algorithm tends to pick somewhat early compared to an experienced analyst. Nevertheless, the Allen picker is a very robust and reliable algorithm. This sophisticated picking algorithm exploits informations provided by the CF as well as by the filtered seismogram. An advantage of the algorithm is that an automatic quality estimation of the P onset is implemented. The speed of the algorithm makes it also suitable for real-time picking of P phases.

When applying this algorithm, the parameters listed in Tab. 16.1 have to be tuned. These parameters are, of course, different for local, regional and teleseismic events and hence depend on the sampling frequency and the applied filter. The outer right columns in Tab. 16.1 show the values used for the presented example waveforms in Fig. 16.4, while the parameter ranges given in column “Values” are taken from Allen (1978).

**Fig. 16.2** Visualization of parameters and thresholds needed for the Allen picker. a) Bandpass filtered (Butterworth 3<sup>rd</sup> order, 2-10 Hz) vertical component seismogram (blue) with automatically estimated P onset (red). b) Corresponding approximated, squared envelope function (blue) with estimated P onset (red). c) STA values of Allen's envelope function (blue) and corresponding reference levels  $\gamma = LTA \cdot C5$  (red). d) STA values of Allen's envelope function (blue) and corresponding continuation criterion  $\delta$  (red). e) Termination number  $L$  (blue) and number of observed zero crossings with drops below the continuation criterion  $\delta$  (black). When the termination number  $L$  and the number of observed zero crossings with  $STA < \delta$  intersect, the signal is supposed to be over. For details, see text and flow chart (Fig. 16.3).

**Fig. 16.3** Flow chart of Allen's picking algorithm. See text for details.

**Fig. 16. 4** Automatically derived P onsets (blue vertical lines) using Allen's algorithm applied to waveforms of local, regional and teleseismic events (black). Applied filtering and epicentral distances are given at top of each panel. Allen's CF (STA values of squared envelope function) is plotted in red. To the right zoomed in portions of waveforms and CFs in the vicinity of the P onset. The green vertical lines indicate the corresponding manual picks. The differences between manual P readings and automatically estimated onset times are less than 0.5 seconds for these local and regional waveform examples. For the teleseismic event waveform examples the differences are 1.7 and 4.2 seconds, respectively.

### 16.3.2 The Baer and Kradolfer picker

Another widely used picking algorithm is the one proposed by Baer and Kradolfer (1987). This algorithm is frequently applied, e.g. by PITSA ("Programmable Interactive Toolbox for Seismological Analysis", Scherbaum and Johnson, 1992) and the picking system MannekenPix (Aldersons, 2004).

Baer and Kradolfer modified Allens' envelope function  $E(t)$  to

$$E_i^2 = x_i^2 + \frac{\sum_{j=1}^i x_j^2}{\sum_{j=1}^i 1}. \quad (16.4)$$

By squaring this envelope function and implementing the variance of  $E(t)$ , they obtain the following CF:

$$CF_i = \frac{E_i^4 - \overline{E_i^4}}{\sigma^2(E_i^4)} \quad (16.5)$$

where  $\overline{E_i^4}$  is the mean of  $E_i^4$  from  $j$ -th sample to  $i$ -th sample and  $\sigma^2(E_i^4)$  is the variance of  $E_i^4$  from sample  $j$ -th to sample  $i$ . As will be shown later, this CF is quite similar to the kurtosis, a parameter to quantify deviations from a Gaussian distribution. Tests on synthetic data using this CF are shown in Fig. 16.5. In contrast to Allen's squared envelope function this CF is sensitive to changes in amplitude, frequency as well as in phase.

**Fig. 16.5** The Baer and Kradolfer CF (blue) for synthetic data (black) with change in amplitude (top), change in frequency (middle) and change in phase (bottom). The CF proposed by Baer and Kradolfer is sensitive to the three types of changes

A pick flag is set if  $CF_i$  exceeds a threshold  $\gamma \approx 10$ . In order to avoid detecting short-term increases caused by noise, a signal is only accepted if the CF does not drop below the signal threshold for times larger than the dominating period. The variance  $\sigma_i^2(E_i)$  is continuously updated, except when  $CF_i$  exceeds a second dynamic threshold  $\delta \approx 2 \cdot \gamma$ . If the CF decreases within a certain time “tup”, the provisional pick is cleared. However, due to the complexity of seismic signals, drops of the CF below the threshold  $\gamma$  for “tdown” seconds are allowed.

Fig. 16.6 shows an example of the proposed CF, calculated for the recording of a local event. In this specific case the derived onset is somewhat late compared to the manual P reading.

**Fig. 16. 6** Example of the Baer and Kradolfer CF (red) calculated for a local event waveform (black). The blue vertical line indicates the automatically derived P onset, the green vertical line the manual P reading.

Tab. 16.2 shows the parameters to be adjusted when applying the Baer and Kradolfer picker, with the right-hand side columns giving the respective values used for the example waveforms of a local, regional and teleseismic event in Fig. 16. 7.

**Tab. 16.2** Parameters to be adjusted when applying the Baer and Kradolfer picker with the respective case values of the parameters used for the example waveforms in Fig. 16.7.

| Parameter | Remark                                                                              | Values                     | Local | Regional | Tele |
|-----------|-------------------------------------------------------------------------------------|----------------------------|-------|----------|------|
| $\gamma$  | threshold                                                                           | 10                         | 10    | 5        | 2    |
| $\delta$  | threshold for updating $\sigma^2$                                                   | $2 \cdot \gamma$           | 20    | 10       | 10   |
| tup       | time [s] for CF to remain above threshold $\gamma$                                  | $>0.3$                     | 1.5   | 1.5      | 2    |
| tdown     | allowed time [s] for CF to drop below threshold $\gamma$ without clearing pick flag | mean of corner frequencies | 10    | 10       | 10   |

**Fig. 16.7** Examples of waveforms of local, regional and teleseismic events and of the Baer and Kradolfer CF. Applied filtering and epicentral distances are given at the top of each panel. The green vertical lines indicate the manual P picks, while the blue vertical lines indicate the automatically estimated P-onset times. The differences between manual and automatic picks are less than 0.2 seconds for these local and regional waveform examples. For the two teleseismic event waveform examples the differences are 0.7 and 2.8 seconds, respectively.

All automatically derived P onsets are in good agreement to the corresponding manual ones. However, it has been shown that this algorithm tends to be somewhat late compared to manual P readings (e.g. Sleeman and van Eck 1999; Küperkoch et al. 2010). Aldersons (2004) integrated the Baer and Kradolfer picker in the picking system MannekenPix and introduces a delay correction. The idea for the correction is to shift the automatic onset back in time as long as the CF decreases significantly towards earlier samples. The delay correction stops when  $CF_i - CF_{i-1}$  is smaller than 0.01, or when this condition cannot be met after moving back the onset by 3 samples. Aldersons states, that this simple correction usually provides “good to very acceptable results” for local earthquakes recorded by short-period instruments.

The Baer and Kradolfer picker is a fast and robust routine, which is also suitable for online detection. Baer and Kradolfer do not propose an automatic quality assessment. However, this algorithm yields high quality picks and was supplemented by the sophisticated quality assessment system MannekenPix (Aldersons, 2004; Di Stefano et al., 2006). Furthermore, the application of this algorithm is quite “user friendly” due to the low number of parameters to be set.

### 16.3.3 P-onset determination using Higher Order Statistics

When an earthquake signal arrives, the statistical properties of a seismogram change abruptly. Therefore, measurements of statistical properties in a moving window are suitable for the determination of a CF and subsequent estimation of arrival times. The statistical properties of the seismogram might be characterized by its distribution density function and by parameters like variance, skewness and kurtosis. The latter two are parameters of higher order statistics (HOS) and defined as follows (e.g. Hartung, 1991).

The expectation of a continuous distribution is given by

$$E[X] = \int_{-\infty}^{\infty} xp(x)dx \quad (16.6)$$

with the distribution function  $p(x)$  of the random variable  $X$ .

Using the expectation the statistic moment  $\alpha$  of order  $k$  of the random variable  $X$  is defined as:

$$\alpha_k = E[X^k] = \int_{-\infty}^{\infty} x^k p(x)dx. \quad (16.7)$$

By analogy the central statistic moment  $m$  of order  $k$  is defined as:

$$m_k = E[(X - E[X])^k], k > 1. \quad (16.8)$$

The second central moment is the variance, the lowest moment yielding informations about the variability of a random variable:

$$Var[X] := E[(X - E[X])^2] = m_2. \quad (16.9)$$

The variance defines the mean power of the alternating part of an ergodian process.

Using the third central moment the skewness becomes:

$$S = \frac{E[(X - E[X])^3]}{E[X - E[X]]^{3/2}} = \frac{m_3}{m_2^{3/2}} \quad (16.10)$$

S becomes zero if the distribution is symmetrical. It becomes negative (positive) if the distribution shows outlayers to the left (right) of the expectation value. The skewness provides information about positive or negative deviations of the distribution density function from the expectation value.

The kurtosis is defined using the fourth central moment:

$$K = \frac{E[(X - E[X])^4]}{E[X - E[X]]^{4/2}} = \frac{m_4}{m_2^2}. \quad (16.11)$$

K is 3 for normally distributed random variables.

An estimation of a central moment from a random sample  $x_j$ ,  $j = 1, K$ ,  $N$  is:

$$\hat{m}_k = \frac{1}{N} \sum_{j=1}^N (x_j - \bar{x})^k. \quad (16.12)$$

Estimations of the variance, skewness and kurtosis are hence given by:

$$\hat{\sigma}^2 = \hat{m}_2 = \frac{1}{N} \sum_{j=1}^N (x_j - \bar{x})^2 \quad (16.13)$$

$$\hat{S} = \frac{\hat{m}_3}{\hat{m}_2^{3/2}} \quad (16.14)$$

$$\hat{K} = \frac{\hat{m}_4}{\hat{m}_2^2} \quad (16.15)$$

Tab. 16.3 shows some example spot checks and their corresponding estimates of variance, skewness and kurtosis. Especially skewness and kurtosis show the potential to detect even small outliers. The first two examples show symmetrically distributed spot checks. The estimated skewness is zero. In the second example the variance increases, though no outlier distorts the distribution. The skewness remains zero and kurtosis increases only slightly. In the third example the outlier is clearly indicated by skewness and kurtosis, while the estimate of the variance remains the same as for the second example.

**Tab. 16.3** Examples of spot checks and corresponding values for variance, skewness and kurtosis.

| Spot Check              | $\hat{\sigma}^2$ | $\hat{S}$ | $\hat{K}$ |
|-------------------------|------------------|-----------|-----------|
| $[1, -1, 1, -1]$        | 1                | 0         | 1         |
| $[1, -1, 2, -2]$        | 2.5              | 0         | 1.36      |
| $[1, -1, 1, -\sqrt{7}]$ | 2.5              | -1.11     | 2.08      |

Fig. 16.8a shows the distribution density function of real background noise. Variance, skewness and kurtosis are calculated in a moving window with a length of 20 seconds. Skewness and kurtosis indicate an almost Gaussian distribution. As soon as the moving window reaches a signal onset (Fig. 16.8b), the shape of the distribution density function changes abruptly and deviates from a Gaussian distribution. Kurtosis and skewness increase strongly.

**Fig. 16.8** **a)** Background noise (top) and corresponding distribution density function (middle), calculated in a moving window of 20 seconds length (dashed box). Bottom: estimated variance, skewness and kurtosis (normalized).

**b)** The moving window reaches a signal onset. The distribution density function is no longer Gaussian shaped, variance, skewness and kurtosis increase strongly.

Longbottom et al. (1988) used higher order statistics (HOS) for the deconvolution of seismic data and called their algorithm a simplified minimum entropy deconvolution method. Saragiotis et al. (2002) suggest to estimate skewness and kurtosis in a moving window to pick P-wave arrival times. Gentili and Bragato (2006) and Gentili and Michelini (2006) used skewness, kurtosis and a combination of skewness and kurtosis and their time derivatives as input for a neural network trained to estimate P-arrival times. Groos and Ritter (2009) used higher order statistics to classify broadband urban noise (USN).

Using eqs. (16.14) and (16.15), skewness and kurtosis are estimated in a moving window. This yields the CF from which the arrival times of the P wave is determined. In order to make the calculation fast, a recursive procedure is suggested:

Let  $\{x(j)\}$  be a zero-mean, stationary process,  $T$  the length of the moving window and

$$N = T/dt + 1, \quad (16.16)$$

the number of samples of the moving window, with  $dt$  being the sampling interval. The actual value for the central moment of order  $k$  of the moving window is:

$$\hat{m}_k(j) = \frac{1}{N} \sum_{l=0}^{N-1} x_{j-l}^k. \quad (16.17)$$

Its estimate at sample  $j$  may be calculated from the previous estimate at sample  $j-1$ :

$$\hat{m}_k(j) = \hat{m}_k(j-1) - (x^k(j-N) + x^k(j)) / N. \quad (16.18)$$

Using eqs. (16.14) and (16.15) skewness and kurtosis are calculated from recursively estimated central moments. Computation times may be decreased by a factor of about 10.

In Fig. 16.9 CFs calculated using skewness and kurtosis are compared to the CF of an STA/LTA for synthetic data with a change in amplitude, frequency and phase, respectively. The test indicates the strong sensitivity of skewness and kurtosis for changes in amplitude. While changes in frequency are detected by skewness and kurtosis, there is only a marginal detectability of changes in phase.

**Fig. 16.9** Tests on synthetic data (black) with changes in amplitude (top), frequency (middle) and phase (bottom). Green: skewness, red: kurtosis, blue: STA/LTA.

From the CF arrival times are determined. Küperkoch et al. (2010) propose a sophisticated, iterative algorithm, which is organized into four stages. A detailed description of the algorithm and the parameter settings is given in their paper. The algorithm might briefly be described as follows:

(1) A CF using skewness or kurtosis is calculated from a bandpass filtered waveform (2-10 Hz for local to regional events). In analogy to Maeda (1985) the Akaike Information Criterion (AIC, Akaike, 1971) is calculated, yielding a first approximate P onset, which is the minimum of the AIC function (Fig. 16.10b).

(2) Using this preliminary P onset, the CF is recalculated around the initial onset in a smaller window, considering a higher frequency content (e.g. 2-15 Hz). The picker searches then for a common local minimum of a smoothed and the unsmoothed CF as this indicates a P-wave onset. The search is carried out to the right and to the left of the initial P onset within a certain pick window. If local minima are found on both sides of the initial P onset, the lower common minimum with lower amplitude of the CF is assumed to coincide with the true P-arrival time (Fig. 16.10c).

(3) For automatic quality assessment the slope of the CF right after the determined phase onset and the signal-to-noise ratio (SNR) serve as two quality criteria (Fig. 16.10c).

(4) Erroneous P onsets are found by checking the signal length and comparing the energy of the vertical component with the energy of the horizontal components to get rid of S picks, spuriously picked as P onsets. Furthermore, the consistency of automatically picked P onsets is checked. The difference between the picks should be lower than a certain threshold and the individual P picks should not have a strong influence on the estimate of the variance of the P picks. This is tested by a Jackknife procedure.

**Fig. 16.10** Automatic determination of a P onset in a 2-10 Hz bandpass filtered, local event waveform (a, black) using the iterative picking algorithm proposed by Küperkoch et al. (2010). The manual P reading is indicated by the dashdotted vertical line. (b) Zoomed in portion of the waveform (black), also showing the CF calculated using kurtosis (red), the unsmoothed AIC function (cyan) and the smoothed AIC function (blue). The initial P onset (dashed vertical line) is determined from the two AIC functions. (c) Zoomed in waveform (black), recalculated, unsmoothed CF (red) using kurtosis, calculated from 2-15 Hz bandpass filtered data, and recalculated, smoothed CF (blue). The green line indicates the slope fitted to the unsmoothed CF. The noise window  $T_{noise}$  and the signal window  $T_{signal}$  are used for SNR estimation.  $T_{noise}$  is 2 seconds.

Fig. 16.11 shows applications of the picking algorithm using kurtosis to local, regional and teleseismic events. For local and regional waveform examples the automatically derived P onsets show less than 0.2 seconds deviation from the manual picks. For the teleseismic waveform examples the differences are 0.7 and 3.2 seconds, respectively.

**Fig. 16.11** Examples for waveforms of local, regional and teleseismic events and the corresponding characteristic functions determined using kurtosis. Applied filtering and epicentral distances are given at the top of each panel. The green vertical lines indicate the manual P picks, the blue vertical lines the automatically derived P-onset times. While the differences between manual picks and automatically P-arrival time estimates are less than 0.2 seconds for the local and regional waveform examples, the differences for the teleseismic waveform examples are 0.7 and 3.2 seconds, respectively.

Skewness and kurtosis are very sensitive to changes in amplitude, while changes in frequency or phase are hardly detectable. The proposed picking algorithm yields very accurate P readings in combination with a reliable quality assessment. Due to the recursive calculation of higher order central moments, this approach is also suitable for onset detection. The length of the moving window for kurtosis and skewness calculation typically range between 2 and 20 seconds, depending on the dominating frequency from which the window should include not less than about approx. 1.5 oscillations.

Skewness and kurtosis are successfully applied by Saragiotis et al. (2002) to 44 seismic events. The corresponding P onsets are compared to manual derived P onsets as well to automatically derived P onsets using Allen's algorithm (see sub-section 16.3.1). The comparison yields better results for the HOS approach. Furthermore, a large scale comparison was performed by Küperkoch et al. (2010) using more than 3000 manually derived P onsets of local to regional events. They found for their data set excellent results when using kurtosis and outperformed the additionally applied picking algorithms proposed by Allen and Baer and Kradolfer (see sub-section 16.3.2).

### 16.3.4 The AR-AIC picker

A stochastic time series, in which the  $i$ -th sample is described as a linear combination of the  $p$  predecessors, is called an autoregressive process of order  $p$ , which can be abbreviated as AR( $p$ ). The mathematical representation is

$$x_m = \sum_{m=1}^p a_m x_{m-j} + \varepsilon_m, \quad (16.19)$$

with  $E[x]=0$ , where  $a_m$  are the coefficients or parameters of the AR process and  $\varepsilon_m$  white noise. Eq. (16.19) can be rewritten as

$$x_m = a_1 x_{m-1} + \dots + a_p x_{m-p} + \varepsilon_m. \quad (16.20)$$

When an earthquake signal arrives, the characteristics of a seismogram, such as variance and the spectrum, change abruptly. For the estimation of a phase arrival, it is assumed that each of the segments before and after the arrival of the seismic wave is stationary and might be expressed by an autoregressive model as follows (e.g. Kitagawa et al., 2001):

noise model (1<sup>st</sup>, pre-onset segment, for  $n=L, \dots, k$ ):

$$x_n^1 = \sum_{m=1}^M a_m^1 x_{n-m} + \varepsilon_n^1 \quad (16.21)$$

signal model (2<sup>nd</sup>, post-onset segment, for  $n=k+L, \dots, N$ ):

$$x_n^2 = \sum_{m=1}^L a_m^2 x_{n-m} + \varepsilon_n^2 \quad (16.22)$$

where  $k+1$  is the change point between the two segments (i.e. the phase arrival),  $a_m^1$  and  $a_m^2$  are the AR coefficients,  $\varepsilon_n^1$  and  $\varepsilon_n^2$  represent gaussian distributed noise in the two segments, and  $M$  and  $L$  are the orders of the AR processes of the noise and the signal model, respectively, which are all unknown parameters. In the following we briefly outline the estimation of these parameters and show an application of locally, stationary segments and its description with autoregressive processes.

Waveforms of seismic phases show usually a higher complexity than that of the preceding noise and should therefore be described by a larger number of AR parameters, i.e., by an AR model of higher order  $p$  (e.g. Leonard and Kennett, 1999). Leonard and Kennett (1999) obtain the order of the AR process by fitting AR power spectra to noise and signal power spectra. Another approach of estimating the order of an AR process (called model identification) is the use of the (empirical) partial autocorrelation function (PACF, e.g. Box et al., 1994). While the (empirical) autocorrelation function (ACF) gives the relation between the actual value of a time series and a later (earlier) value (delayed with time lag  $\tau$ ), not taking into account the influence of interjacent values, the PACF gives the direct correlation between lag- $k$  distant values by removing the influence of interjacent values. For an AR process of order  $p$  the PACF will be nonzero for time lags  $l$  less than or equal  $p$  and zero for time lags  $l > p$  and hence gives informations about the order of an AR process. Akaike (1970) proposed the final prediction error (FPE) to estimate the model order.

Fig. 16.12a) and 16.12b) show the pre-event noise window, the signal onset and the corresponding empirical ACF as well as the empirical PACF, from which the order of the process is estimated. The order of the time series incorporating the signal onset is much higher than that for the noise window. The PACF is assumed to be zero if the PACF is smaller than the standard S.E., which is  $S.E. = 1/\sqrt{N}$  (e.g. Box et al., 1994), where  $N$  is the number of observations. PACF and FPE yield the same model orders.

**Fig. 16.12** a) Pre-event portion of a seismogram, corresponding ACF and PACF for sample lags 0 to 20, and FPE as a function of model order. The order of the AR process can be obtained from the PACF. The last value of the PACF which is larger than the standard error (dashed line) occurs at sample lag 3. The order of the AR process is therefore 3. The FPE

function also gives a local minimum at model order 3. **b)** Pre-event portion, seismic phase onset, corresponding ACF and PACF for sample lags 0 to 20, and FPE as a function of the model order. The order of the AR process is estimated to be 5, as the last value of the PACF, which is larger than the standard error, is at sample lag 5, indicating a higher complexity of the seismic signal compared to the preceding noise. Also the FPE gives a local minimum at model order 5.

However, the estimation of the order of an AR process is very uncertain, and hence in most AR applications a fixed AR order is used, estimated with the introduced procedure or by trial and error (e.g. Leonard and Kennett, 1999).

The so called autoregressive-Akaike-Information-Criterion-picker (AR-AIC) proposed by Sleeman and van Eck (1999) is based on the work by Akaike (1971, 1974), Morita and Hamaguchi (1984) and Takanami and Kitagawa (1988). A longer time series is divided into two locally stationary segments each modeled by an AR process. The first segment represents noise, the second segment contains the signal. The picking algorithm can be described by five steps: (1) Bandpass filtering of the seismogram, (2) detection of a seismic phase using an STA/LTA detector, (3) estimation of two sets of AR parameters, namely for noise and signal, respectively, (4) calculation of two prediction errors using the AR parameters for noise and signal, respectively, (5) the minimum of the two-model AIC indicates the arrival time. For the following detailed description of the picker algorithm we assume that due to a first rough estimation of the P-wave arrival time the time series  $x_n = x_1, \dots, x_N$  can be divided into two subseries: the first represents noise, the second the seismic phase (signal). Thus, starting point for the following derivation are eqs. (16.21) and (16.22). Furthermore, we assume a fixed order  $M$  for both models, estimated by trial and error or the use of the PACF.

As we assume Gaussian distributions of  $\varepsilon_n^1$  and  $\varepsilon_n^2$ , we can write for the two corresponding likelihood functions:

$$l(\varepsilon_n^1) = \frac{1}{\sigma_1 \sqrt{2\pi}} e^{-\frac{(\varepsilon_n^1)^2}{2\sigma_1^2}} \quad (16.23)$$

$$l(\varepsilon_n^2) = \frac{1}{\sigma_2 \sqrt{2\pi}} e^{-\frac{(\varepsilon_n^2)^2}{2\sigma_2^2}} \quad (16.24)$$

The approximate likelihood of the locally stationary AR model in the intervals  $[M+1, k]$  and  $[k+1, N-M]$  is hence given by

$$L(x, M, a_m^i, \sigma_i^2 (i=1,2)) = \prod_{i=1}^2 \left( \frac{1}{\sigma_i^2 2\pi} \right)^{\frac{N_i}{2}} \exp \left( -\frac{1}{2\sigma_i^2} \sum_{n=p_i}^{q_i} \left( x_n - \sum_{m=1}^M a_m^i x_{n-m} \right)^2 \right) \quad (16.25)$$

with  $p_1 = M+1$ ,  $p_2 = k+1$ ,  $q_1 = k$ ,  $q_2 = N-M$ ,  $n_1 = k-m$  and  $n_2 = N-M-k$ . The condition for maximum likelihood estimates of the model parameters is

$$\frac{\partial \log(L(x, M, a_m^i, \sigma_i^2))}{\partial (a_m^i, \sigma_i^2)} = 0, \quad (16.26)$$

which yields

$$\sigma_{i,max}^2 = \frac{1}{n_i} \sum_{j=p_i}^{q_i} \left( x_j - \sum_{m=1}^M a_m^i x_{j-m} \right)^2. \quad (16.27)$$

Note, that the second sum is equivalent to the prediction error.

By substituting eq. (16.27) into eq. (16.25), the maximum of the logarithmic likelihood function  $\log(L(k, x, M, a_m^i, \sigma_i^2))$  for the two models as function of division point  $k$  becomes:

$$\log(L(k, x, M, a_m^i, \sigma_i^2)) = -\frac{1}{2}(k-M)\log(\sigma_{1,max}^2) - \frac{1}{2}(N-M-k)\log(\sigma_{2,max}^2) + C \quad (16.28)$$

where  $C$  is a constant. In the case of the locally stationary AR model, the AIC, which is a criterion for the selection of the best statistical model, is given by (Akaike, 1971):

$$AIC = -2(\text{maximum log likelihood}) + 2(\text{number of parameters}),$$

where the number of parameters is given by the model order. For the merging point  $k$ , which separates the two models, the AIC becomes:

$$AIC(k) = AIC^1 + AIC^2 \quad (16.29)$$

and thus:

$$AIC(k) = (k-M)\log(\sigma_{1,max}^2) + (N-M-k)\log(\sigma_{2,max}^2) + C_1 \quad (16.30)$$

where  $C_1$  is a constant. The minimum of the AIC points then to the optimal separation time of the two stationary time series and indicates the arrival time of the phase. The AR coefficients  $a_m^i$  in eq. (16.27) are estimated in advance separately for the noise and the signal model, respectively. This is usually accomplished by either the Yule-Walker approach (e.g. Box, 1994), Burgs algorithm (Burg, 1975), or the least-squares approach.

In the following the AR-AIC picker is applied to synthetic and real test waveforms. The AR coefficients of the noise and the signal models are estimated in windows of 4 seconds length. The window of the noise model starts 4 seconds before the initial estimate of the arrival time. The window for the estimation of the AR parameters of the signal starts at the initial estimate of the arrival time (Fig. 16.13, top). The picker searches for the minimum in eq. (16.30) in a time window of 12 seconds length starting 8 seconds before the initial STA/LTA detection (Fig. 16.13, bottom). Sleeman and van Eck (1999) fixed the order of the two AR models to 8. Leonard (2000) used an order 4 AR model for both signal and noise.

**Fig. 16.13 Top:** Waveform of a local event (black) and an initial P-onset detection (blue) derived from STA/LTA ratios (red). The green vertical lines indicate the time interval for noise level estimation. The dashed lines denote the time windows for determination of AR coefficients for the noise and the signal model, respectively (NW and SW). **Bottom:** Waveform (black) around the initial STA/LTA pick (red,dashed line) and the automatically determined P onset (red line). Green: The AIC as a function of the merging point  $k$ , determined using eq. (16.30).

Fig. 16.14 shows the results for the synthetic data. For this test, we reduced the assumed order of the AR process to 2. The test shows clearly the potential of AR algorithms to detect changes in amplitude, frequency as well as in the phase.

**Fig. 16.14** AR-AIC (red) as function of the merging point  $k$  for synthetic data (black) with changes in amplitude (top), changes in frequency (middle), and changes in phase (bottom). The assumed order of the AR process is reduced to 2. Changes in the time series are recognized in all three cases.

**Tab. 16.4** Parameters to be adjusted for the AR-AIC picker. Parameter settings applied for STA/LTA trigger used to get initial the P onset are not shown. The outer right columns represent the values used for the example waveforms in Fig. 16.15.

| Parameter      | Remark                                                       | Values | Local | Regional | Tele |
|----------------|--------------------------------------------------------------|--------|-------|----------|------|
| <i>tseg1</i>   | length of 1 <sup>st</sup> segment for calculating AIC(k) [s] | 4      | 8     | 8        | 50   |
| <i>tseg2</i>   | length of 2 <sup>nd</sup> segment for calculating AIC(k) [s] | 4      | 4     | 4        | 40   |
| <i>tnoise</i>  | length of noise window for AR-coefficient determination [s]  | 4      | 4     | 4        | 50   |
| <i>tsignal</i> | length of signal window for AR-coefficient determination [s] | 4      | 4     | 4        | 50   |
| <i>offset1</i> | offset between initial pick and <i>tnoise</i> [s]            | 4      | 4     | 4        | 50   |
| <i>offset2</i> | offset between initial pick and <i>tsignal</i> [s]           | 0      | 0     | 0        | 0    |

Fig. 16.15 shows applications of the AR-AIC picker to real local, regional, and teleseismic waveform data. Tab. 16.4 summarizes the parameters used for the example waveforms in Fig. 16.15 and the parameters proposed by Sleeman and van Eck (1999).

One shortcoming of this picker is the dependency on the STA/LTA trigger, which may be exchanged by a more robust procedure. The weighting scheme based on signal-to-noise ratios is useful for detecting false picks, but does not yield reliable quality estimates of the onset. However, the shape of the AIC function depends on the “sharpness” of the onset and could thus serve as a quality criterion (Diehl et al., 2009b, electronic supplement). The AR-AIC picker is more expensive but also more powerful than the Allen picker and the Baer and Kradolfer picker due to its strong sensitivity to changes in the waveform. Furthermore, this picking algorithm represents a robust tool for the identification of a first arrival.

**Fig. 16.15** Waveform examples of local, regional and teleseismic events and the corresponding characteristic functions for the AR-AIC picker proposed by Sleeman and van Eck (1999). Applied filtering and epicentral distances are given at top of each panel. The initial pick is determined by a STA/LTA detector. AIC as a function of the merging point is shown in red. The blue vertical lines denote the automatically determined P-phase arrival times, the green vertical lines the manual P picks. For local event waveform examples, the differences between manual picks and automatically estimated P-arrival times are 0.05 and 0.01 seconds, for regional waveform examples 0.34 and 0.28 seconds, and for teleseismic waveform examples 2.7 and 1.8 seconds, respectively.

### 16.3.5 Discussion of presented P-picking algorithms

The previous section presented four widely used P-picking algorithms in great detail. However, for potential users it might be difficult to decide which algorithm to choose for his certain data set. Therefore, we try to summarize the pros and cons of the four presented algorithms.

The Allen picker is a fast and robust algorithm, which also accounts for automatic quality assessment. However, as this algorithm is amplitude based only, it might miss emergent P onsets. A comparative study by Küperkoch et al. (2010) showed that this algorithm tends to pick somewhat early compared to what an analyst would pick.

The Baer and Kradolfer picker is also very fast and robust and quite user-friendly, as this algorithm only needs 4 input parameters. A shortcoming of this algorithm is the missing automated quality assessment. Several comparative studies (Sleeman and van Eck 1999, Aldersons 2004, Küperkoch et al. 2010) showed that this picking algorithm tends to be somewhat late compared to manual P picks.

Though only amplitude based too, higher order statistics are quite sensitive even to emergent P onsets. In combination with a sophisticated picking algorithm (e.g. Küperkoch et al. 2010), which exploits the entire information provided by the determined CF, yields excellent results. If precisely tuned, the automated quality assessment proposed by Küperkoch et al. (2010) gives similar weights as the analysts. However, the choice of the various parameters needed for this sophisticated algorithm is quite difficult and needs some experience.

The AR-AIC picker is a highly sophisticated picking algorithm based on information theory. The algorithm is computationally quite expensive and hence much slower than the other presented picker. In the discussed version by Sleeman and van Eck (1999) the initial P onset is derived from an STA/LTA detector, which might miss emergent P arrivals or P-phase arrivals dominated by instantaneous changes in frequency. This may limit the performance of this picking algorithm, and it might be worthwhile to replace the STA/LTA detector with a more robust, but nevertheless fast picker like the Baer and Kradolfer picker or a picking algorithm based on higher order statistics. Furthermore, the implemented quality assessment in the Sleeman and van Eck version based on signal-to-noise ratio only is not sufficient for robust quality estimation of the derived P onsets. A more robust quality criterion might be the “sharpness” of the AIC function, as proposed by Diehl et al. (2009b). However, a multivariate improvement of the AR-AIC picker should also be able to pick precisely S-arrival times.

## 16.4 Automated S-onset determination

For robust location of earthquakes and especially for the determination of hypocentral depths, the estimation of S-onset times is crucial (Gomberg et al., 1990). Furthermore, S-wave arrival times may be inverted for models of the S-wave velocity supplementing P-wave velocity models and yielding additional information e.g. for petrological interpretation and seismic hazard models. However, S phase picking is more difficult than P-phase picking due to the character of the later arriving shear wave. Although by far most of the seismic wave energy is contained in the S waves and accordingly their amplitudes are generally larger than those of the related P waves (see record examples of local, regional and teleseismic events in DS 11.1-11.3), the often weaker very initial S-wave onset is usually buried in the preceding P coda.

Statistical properties of the P coda are highly variable and usually not Gaussian distributed. Therefore, the S onset may not be detectable by algorithms based on higher order statistics. S waves show often emergent onsets and may be preceded by S to P conversions. Moreover, while the energy of longitudinally polarized P waves is usually concentrated on the vertical component, the energy of the later arriving transversally polarized S waves is in general distributed over all three components. In addition, the occurrence of S-wave splitting may complicate the determination of the S-wave arrival time (Fig. 16.16). Thus, even manual picking and phase identification is often uncertain and inconsistent and experience is needed to pick and identify reliably the S onset. Hence, automated S-phase arrival time estimation is a challenging task and the development of optimized automated algorithms for picking of arrival times of S phases or other later arriving phases is a topic of ongoing research and applications to large data sets are still rare.

Reliable automatic S-onset determination makes use of all components or at least of both horizontal components. Usually, automatic picking of later phases is an iterative process. First the P onset has to be determined using the vertical component, from which a time window for S-phase picking is derived. Alternatively, the S phase is picked in a time window predicted from a preliminary event location. Algorithms proposed for P phase picking may also be used for S-phase arrival time determination when applied to transversal components. For instance, the AR-AIC picker (Takanami and Kitagawa (1988, 1991), Sleeman and van Eck (1999), see sub-section 16.3.4), has the potential of picking later phases if applied to horizontal components. Leonard and Kennett (1999) investigated single- and multi-component autoregressive modeling techniques for P- as well as for S-onset time determination. For multi-component analysis, the AR coefficients are represented by a second-order tensor. The order of the autoregressive processes representing the noise and the signal parts of the seismogram, respectively, are obtained by fitting AR-power spectra to observed ones.

**Fig. 16.16** Shear-wave splitting observed on a 2-10 Hz bandpass filtered local event recording. The green line indicates the SH-onset time, visible only on the north-south component. The red line indicates the SV-onset time, visible on the vertical and the east-west component.

Here, the algorithms proposed by Cichowicz (1993), Wang and Teng (1997) and Diehl et al. (2009b) are discussed in detail, as these algorithms are specifically developed for S-phase arrival time determination.

Cichowicz (1993) proposed an algorithm for automatic S-phase picking from three-component seismic data based on a polarization analysis, which is a powerful tool to distinguish between longitudinal and transversal energy, as discussed above. The algorithm might be described as follows:

Taking into account the dominating frequency, usually determined from displacement or velocity power spectrum, respectively, the length  $N$  of a moving window is determined. At first, the covariance matrix of the three orthogonal components of ground motion is computed within a window around the P onset, which is assumed to be known:

$$\begin{bmatrix} COV(X,X) & COV(X,Y) & COV(X,Z) \\ COV(Y,X) & COV(Y,Y) & COV(Y,Z) \\ COV(Z,X) & COV(Z,Y) & COV(Z,Z) \end{bmatrix} \quad (16.31)$$

where the estimate of the covariance for  $N$  observations of two variables  $X$  and  $Y$  is given by

$$COV(X,Y) = \frac{1}{N} \sum_i^N (x_i - \bar{x})(y_i - \bar{y}) \quad (16.32)$$

with  $\bar{x}$  and  $\bar{y}$  being average values. The direction of polarization is calculated by considering the eigenvector associated with the largest eigenvalue. Then, the X, Y and Z components are rotated into L, Q and T components, where L coincides with the principle direction of the P wave particle motion, i.e.

$$\begin{bmatrix} L \\ Q \\ T \end{bmatrix} = \begin{bmatrix} u_{11} & u_{12} & u_{13} \\ u_{21} & u_{22} & u_{23} \\ u_{31} & u_{32} & u_{33} \end{bmatrix} \cdot \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (16.33)$$

where  $u_{i,j}$ ,  $j=1,2,3$ , are the direction cosines of the  $i$ -th principle direction. The covariance matrix and the following parameters are calculated for a moving window:

1) The deflection angle  $F_1(t)$  - the angle between the current polarization and the P-wave polarization - given by

$$F_1(t) = \frac{\cos^{-1} |u_{11}|}{\pi/2} \quad (16.34)$$

with  $u_{11}$  being the direction cosines in the L, Q, T coordinate system.

2) The degree of linear polarization  $F_2(t)$

$$F_2(t) = \frac{(\nu_1 - \nu_2)^2 + (\nu_1 - \nu_3)^2 + (\nu_2 - \nu_3)^2}{2 \cdot (\nu_1 + \nu_2 + \nu_3)^2}, \quad (16.35)$$

with  $\nu_1, \nu_2, \nu_3$  being the eigenvalues of the covariance matrix at time  $t$ .

3) The ratio  $F_3$  between transversal and total energy

$$F_3(t) = \frac{\sum_i^N (Q_i^2 + T_i^2)}{\sum_i^N (Q_i^2 + T_i^2 + L_i^2)} \quad (16.36)$$

These parameters are normalized and their theoretical values will be close to 1 for S waves. The CF is determined using these parameters:

$$CF(t) = F_1^2 \cdot F_2^2 \cdot F_3^2. \quad (16.37)$$

An S phase is declared, if the CF exceeds a threshold  $A$  for a few consecutive samples.  $A$  is calculated from the CF:

$$A = \overline{CF} + 3\sigma, \quad (16.38)$$

where  $\overline{CF}$  is the average value of the CF and  $\sigma$  the variance of the CF in the time window. The uncertainty of the automatic S pick is not evaluated by this algorithm. Sleeman and van Eck (2003) combined the polarization analysis with wavelet tranform (Rioul and Vetterli, 1991) and applied their approach to 313 local events. For their data, they found 44.1% to 47.9% of automatic S picks in the interval  $[-0.5, +0.5]$ s around the manual S onset and 65.5% to 68.9% of automatic S picks in the interval  $[-1.5, +1.5]$ s around the manual S pick.

Wang and Teng (1997) combine several approaches into an artificial neural network (ANN) algorithm. They consider the following properties of the three-component seismogram: (1) short-term to long-term average ratios (STA/LTA); (2) the ratios of transversal to total power (same as  $F_3$  in Cichowicz, 1993); (3) the change of autoregressive model coefficients. As they assume a second-order AR process, this change becomes:

$$ARC(i) = \frac{|a_1(i)a_2(i) - a_1(i-1)a_2(i-1)|}{|a_1(i)a_2(i)|}, \quad (16.39)$$

where  $a_1, a_2$  are the estimated AR coefficients.

(4) The fourth criterion is the deflection angle  $D(t)$  or the short-axis incidence angle of the polarization ellipsoid, i.e.

$$D(t) = \frac{\cos^{-1} |u_{31}|}{\pi/2}. \quad (16.40)$$

In their proposed ANN, each attribute is calculated by a neural subnet. The output of the subnets varies between 0 (no S phase) to 1. The output of the four subnets serve as input for the final decision unit, where the inputs are summed up. If the summation of inputs is larger than 3, the estimated arrival time is accepted.

Similar to their approach, Diehl et al. (2009b) propose a picking algorithm that combines STA/LTA ratios, polarization analysis, and AR-AIC picking (see sub-section 16.3.4). Combined STA/LTA ratios are calculated from both horizontal components as illustrated in Fig. 16.17. The picking algorithm is similar to the one proposed by Baer and Krüger (1987, see sub-section 16.3.2), but yielding an earliest ( $tS_{min1}$ ) and latest ( $tS_{thr1}$ ) possible pick, respectively.

**Fig. 16.17** Combined STA/LTA approach used for S-wave detection on horizontal components. Black solid curves represent the Wood-Anderson filtered three-component seismograms (amplitudes normalized by station maximum) of a local earthquake in Switzerland (Ml 3.1, focal depth of 9 km). The gray shaded trace denotes the combined STA/LTA ratio derived from N and E components.  $tP_{obs}$  represents the known P-arrival time, and  $tS_{pre}$  indicates the position of theoretical S arrival predicted from a regional one-dimensional model. The dashed horizontal line denotes the dynamic threshold  $thr_1$  for the picking algorithm. The S-wave arrival time based on the STA/LTA detector in the potential S window ( $SW1$  to  $SW2$ ) is most likely located in the interval between  $tS_{min1}$  (minimum pick) and  $tS_{thr1}$  (threshold pick). Copy of Fig. 2 in Diehl et al. (2009b, p. 1908) with © granted by the Seismological Society of America.

The polarization detector mainly follows the one proposed by Cichowicz (1993). In addition, they calculate a weighting factor  $W(t)$  for each window, which accounts for the absolute amplitude within the centered window with respect to the maximum amplitude derived from the coarse S window, derived from the observed P onset and the theoretical S onset. The characteristic function CF of the polarization detector is:

$$CF(t) = F_1(t)^2 R(t)^2 F_3(t)^2 W(t), \quad (16.41)$$

with  $F_1$  and  $F_3$  being the deflection angle and the ratio between transversal and total energy, respectively, as introduced above.  $R(t)$  is the rectilinearity:

$$R(t) = 1 - \frac{\nu_2 + \nu_3}{2 \cdot \nu_1}, \quad (16.42)$$

with  $\nu_1, \nu_2, \nu_3$  being again the eigenvalues of the covariance matrix. Fig. 16.18 illustrates the principle of the proposed polarization detector. A picking algorithm is applied to the derived CF, which yields an earliest ( $tS_{min2}$ ) and latest ( $tS_{thr2}$ ) possible estimate of the S phase arrival (see Fig. 16.18).

**Fig. 16.18** Example for the polarization detector. L, Q, and T denote the rotated components. The corresponding S-wave operators are  $D(t)$  (directivity),  $P(t)$  (rectilinearity), and  $H(t)$  (transverse to total energy ratio). The uppermost trace represents the amplitude weighted characteristic S-wave function  $CFS$ . The arrival of the S wave (gray band) goes along with the simultaneous increase of  $D(t)$ ,  $P(t)$ ,  $H(t)$ , and  $CFS$ . Compared to the actual arrival on T, the S wave detection is shifted by approximately 0.1 sec to earlier times. This time shift is caused by the finite length of the polarization filter.  $CFS$  is not affected by the P wave. Copy of Fig. 3 in Diehl et al. (2009b, p. 1910) with © granted by the Seismological Society of America.

The information provided by the detectors is used to set up the search window for a AR-AIC picker, applied to single original and rotated components and to both horizontal components as illustrated in Fig. 16.19. The implementation is mainly based on the method of Takanami and Kitagawa (1988). Finally, the earliest and latest possible picks from the STA/LTA detector, polarization detector, and the different AIC minima are used to estimate the ultimate automatic S-wave arrival time and its corresponding uncertainty. Examples of final automatic S-phase picks of different uncertainty classes are shown in Fig. 16.20.

[info/special\\_datasets.htm](http://www.tensorflow.org/info/special_datasets.htm).

**Fig. 16.19** Example of the AR-AIC picker. All amplitudes are trace normalized. The lower box illustrates the search window configuration centered around  $t_{AC}$ . The corresponding univariate AIC functions are shown for the combination of original E+N components ( $AIC^H$ ) and for the rotated components Q ( $AIC^Q$ ) and T ( $AIC^T$ ). AR-AIC picks  $t_{SAQ}$  and  $t_{SAT}$  derived from the minimum on the AIC functions agree very well with the actual arrival of the S wave visible on the seismograms. The uncertainty of the AR-AIC pick is expressed by the earliest and latest possible arrival times  $t_{SEQ}$ ,  $t_{SET}$ ,  $t_{SIQ}$ , and  $t_{SIT}$  derived from intersection of threshold  $thr_{AIC}$  (dashed horizontal lines) with the corresponding AIC functions. Copy of Fig. 4 in Diehl et al. (2009b, p. 1911) with © granted by the Seismological Society of America.

**Fig. 16.20** Examples of automatic S-wave picks at epicentral distances dominated by first arriving Sg phases (left-hand column) and first arriving Sn phases (right-hand column) for different error intervals. The error interval derived from the automatic quality assessment is represented by the vertical gray bars. The vertical long black bars denote the mean position of the S-wave onset. Error interval and mean position agree very well with the actual S-wave arrival observed on the seismograms. Copy of Fig. 5 in Diehl et al. ## 16.5 Automated quality assessment, phase identification, and outlier detection

Resolution and reliability of travel-time based inversion techniques, like hypocenter determination and tomography, depend strongly on the consistency of data quality weighting. Arrival times with larger uncertainties have to be down weighted or even rejected in the inversion process. Uncertainties of arrival time picks are traditionally divided into discrete quality classes (e.g. 0 to 4, with 0 corresponding to highest quality and 4 corresponding to lowest quality). Each quality class is associated with a certain weight (between 1 and 0) and should correspond to a measured uncertainty interval (in seconds). Such discrete quality classification is still used in many location and tomography algorithms like HYPOINVERSE (Klein, 2002) or VELEST (Kissling, 1988), which convert the quality class to a data weight during inversion. Quantitative uncertainty measures are usually absent for arrival times in global bulletins. Instead, picks are simply classified as “impulsive”, “emergent”, or “questionable” based on wavelet characteristics. Such qualitative error assessment, however, no longer satisfies the resolution capability of modern digital waveform data.

Although often disregarded, the uncertainty of an arrival time pick consists of two components: uncertainty of the phase timing and uncertainty of the phase identification (e.g. Diehl et al. 2009b). Automated picking and association of later phases is challenging, but provides fundamental information on earth structure and hypocenter locations. Especially phases like PmP, S, pP, and sP are crucial to constrain focal depth of local and teleseismic earthquakes.

In this section, we discuss procedures for automatic quality assessment of phase timing and phase identification. Because automatic quality assessment sometimes overestimates the timing quality or misinterprets the phase, outlier picks have to be detected in post-picking procedures as described at the end of this section.

### 16.5.1 Quality assessment of phase timing

Arrival time estimation of phases needs to be accompanied by uncertainty estimates in order to down weight or even reject uncertain picks. The uncertainty of picks may be increased by low signal to noise ratios or by emergent onsets in contrast to impulsive ones. Emergent onsets are caused by the character of the source time function of the earthquake, the radiation pattern or by complicated wave propagation. Until now, only few papers focus on automatic quality assessment (e.g. Allen 1978; Aldersons 2004; Di Stefano et al. 2006; Diehl et al. 2009a and b; Nippres et al. 2010; Küperkoch et al. 2010) though automated arrival time determination should always be supplemented by automated uncertainty estimations.

Most widespread is the use of the signal-to-noise ratio (SNR) for automatic quality control and uncertainty estimation. Using certain window lengths depending on the dominating frequency, the amplitudes or the energy content right before the considered onset is compared to the amplitudes or energy content right after the onset (e.g. Sleeman and van Eck, 1999). If the SNR is calculated in the frequency domain, power spectral densities are compared (e.g. Leonard and Kennett, 1999). However, even bursts of noise may lead to large SNR, resulting in high qualities for false picks. To overcome this problem, it is necessary to estimate the signal length, which can be done by exploiting the envelope function (see Fig. 16.21) or by counting consecutive zero crossings of previous amplitudes, which exceed a certain threshold, as suggested e.g. by Allen (1978, see sub-section 16.3.1).

In addition to criteria for the SNR and the signal length, Allen (1978) uses a quite sophisticated algorithm for estimating the quality, based on analyses of the seismogram as well as of the CF (see sub-section 16.3.1). Küperkoch et al. (2010) suggest using the slope of the CF (sub-section 16.3.3) to identify emergent onsets. The MannekenPix algorithm of Aldersons (2004) includes a pattern recognition scheme, which weights nine different waveform attributes (predictors) obtained in the time window around the automatic pick and classifies the pick in discrete quality classes. The corresponding weighting factors are called “Fisher coefficients”, which have to be calibrated with a set of manually picked arrival times (reference picks).

A multiple discriminant analysis (MDA) is used to derive appropriate Fisher coefficients from the reference picks. Four predictors characterize the SNR. Predictor 5 is the difference between the dominant frequency of the signal and the dominant frequency of the noise. The remaining 4 predictors characterize properties of the CF around the estimated arrival time. This elaborated picking algorithm has been successfully applied to local earthquake data of the Dead Sea region (Aldersons, 2004), Italy (Di Stefano et al., 2006) and the greater Alpine region, respectively (Diehl et al., 2009a).

**Fig. 16.21** Short-period seismogram, 2-10 Hz bandpass filtered (black), and corresponding envelope function (blue). The envelope function is used to confirm the automatically derived P onset. The noise level is calculated within a window (green horizontal line) right before the automatically derived P onset (red vertical line). For this regional waveform example the requirement is that at least 70% of the envelope within a window of 4 seconds should exceed the signal threshold (green vertical line after P onset), which is twice the noise level.

### 16.5.2 Phase identification

Automatically determined arrivals have to be identified, that means, phase names have to be assigned to the arrival times, indicating their fundamental type and path through the earth. Most automatic approaches are intended to pick the first arriving phase of either P or S branches. Therefore, any automatic pick is considered as first arriving phase. In practice, picking algorithms can miss the very first phase and misinterpret later phases or larger amplitudes in the coda as the first arrival. Such phase misidentification may result in errors in the arrival times of up to several seconds, as pointed out e.g. by Diehl et al. (2009a). Fig. 16.22 shows an example of a regional event recording, where Pn is picked by the analyst, while the automated procedure picked a more prominent later phase (likely PmP). In case of first-arrival studies, picks should be accompanied by first-order estimates on whether arrival time is associated with first or later arriving phase. So far, most algorithms do not include such uncertainty estimates of phase identification, however, the assessment of phase timing can be tuned to pick targeted phases as described e.g. by Diehl et al. (2009a).

Explicit phase association of arrival times is usually only possible in combination with *a priori* information on the Earth's structure and the location of the event. Phase identification, however, can be accomplished by an iterative procedure: a preliminary location is determined using first arriving P phases, then first (and later arrivals) are associated by comparison with theoretical arrival times. In addition, epicentral distances can be estimated from S-P times and polarization analysis may support the identification of later phases (see section 16.4).

**Fig. 16.22** Example of phase misidentification within a 2-10 Hz bandpass filtered record. First arriving Pn-phase (blue) and intermediate phase (likely Pg) is missed by the automatic approach using kurtosis. Instead, the automatic approach (green) picks a later phase (likely PmP). Such misidentification may result in errors of several seconds.

Recordings of local to regional earthquakes are dominated by crustal phases like Pg, Pn, and PmP. Later arrivals are often buried in the P and S coda and may occur within short time windows. In addition, the correct identification is challenging due to the heterogeneous structure of the crust, which leads to significant travel time residuals, attenuation, scattering, and interference of these phases. In general, identification of first and later arriving crustal phases requires good knowledge of the three-dimensional structure of the crust. On the other hand, teleseismic events are dominated by mantle and core phases (see Chapter 11) and, as discussed later, signal properties like amplitude ratios between components, polarization or slowness as well as travel time differences between phases may be used to identify phases in the record. Global one-dimensional travel time tables can be used to predict and associate arrival times with phases. Crucial later arriving phases like pP can be associated with probability models as e.g. implemented in the EHB (Engdahl, van der Hilst, Buland) relocation procedure of Engdahl et al. (1998).

*In situ* automatic identification of various phases of a seismic record requires detection algorithms sensitive to later arrivals. Earle and Shearer (1994) propose a detection algorithm based on STA/LTA ratios calculated from the envelope function using the Hilbert transform of the seismogram. In order to prevent rapid fluctuations in the ratio function, the ratio function is smoothed by convolution with a Hanning filter. They applied this algorithm to seven years of global data distributed by the National Earthquake Information Center (NEIC). A comparison with the ISC hand-picked phase arrival times encounters difficulties with phase arrivals characterized by a change in frequency and little or no change in amplitude. However, the proposed algorithm is a useful tool for extracting seismograms containing phases desired for further analysis, e.g. for phase association. Fig. 16.23 shows an application of the proposed algorithm to a regional event recording.

Tong and Kennett (1995) and Bai and Kennett (2000) developed an algorithm, which combines automated detection and phase association for first and later arrivals. The proposed procedures are rather sophisticated and it is beyond the scope of this manual to provide a detailed description. The algorithms include many components useful for development of future generations of automatic algorithms (e.g. data adaptive filtering, analysis of three-component records, pattern recognition, etc.) and therefore we summarize only the main features of their approaches here.

Tong and Kennett (1995) define a set of STA/LTA detectors that make use of all three components and compare STAs and LTAs from different components in order to detect later phases. They use an approach of continual updating (Tong, 1995), where the effective lengths of the STA and LTA windows are adapted to the dominating frequency. In addition, they propose optimized filters to enhance the possibility of later phase detections and detection on multiple frequency bands (see also sub-section 16.6.2). Ratios of the energy on the different components, the frequency content, as well as polarization properties are used to characterize and to identify detected phases. Three measures of the energy of the phases are introduced:

**Fig. 16.23** Application of the proposed algorithm by Earle and Shearer (1994) for phase detection to a regional event recording at distance  $\Delta = 3792$  km (blue). Top: 0.01 – 0.1 Hz bandpass filtered waveform with recognized arrivals (vertical, black lines). Middle: corresponding STA/LTA ratios. Bottom: Smoothed ratio function (SRF, blue), applied threshold (dashed horizontal line) and detections (vertical black lines). This algorithm is useful for the detection of later arrivals rather than the precise arrival time determination.

1. the total energy  $E_3 = Z^2 + N^2 + E^2$ ,
2. the vertical component energy  $V_E = Z^2$ ,
3. the energy in the horizontal plane  $H_E = N^2 + E^2$ .

The LTA measure is calculated for the total energy  $E_3$ , while STA terms are calculated for the energy on each of the  $Z$ ,  $N$ , and  $E$  components as well as for the horizontal energy  $H_E$ , and the

total energy  $E_3$ . This results in a set of five different STA/LTA triggers. The output of the STA/LTAs is used to detect as well as to identify phases. Tong and Kennett (1996) define a range of empirical conditions to identify the fundamental type of the detected phase as summarized in Tab. 16.4.

**Tab. 16.4** Empirical conditions to identify the fundamental type of detected (later) phases proposed by Tong and Kennett (1996). Distance range far-regional to teleseismic is defined by slowness less than  $0.12 \text{ km}^{-1}$ .

| P wave<br>(far-regional to teleseismic) | SV-wave<br>(far-regional to teleseismic) | P wave<br>(regional) |
|-----------------------------------------|------------------------------------------|----------------------|
| $H_E < 0.50E_3$                         | $H_E > 0.50E_3$                          | $H_E > 0.50E_3$      |
| $V_E > 0.35E_3$                         | $V_E < 0.35E_3$                          | $V_E > 0.35E_3$      |

Furthermore, simple indicators are introduced to characterize the waveform of the phases:

$$\begin{aligned}\tilde{P} &= V_E - 0.35E_3, \\ \tilde{S} &= H_E - 0.5E_3.\end{aligned}$$

The set of five STA/LTA phase detectors is applied to the data adaptive high-pass (corner frequency: two times the dominant background noise frequency) as well as low-pass (corner frequency: half the dominant frequency background noise) filtered data.

Polarization properties of the phases are characterized in terms of azimuth and incidence angles of a "phase vector", which is constructed to describe the average behavior of the phase over a quarter cycle of the dominant period. Using these attributes Tong and Kennett (1996) developed a procedure for the identification of phases. It is assumed that the following six attributes are available for the each phase  $i$ :

1.  $t_i$ , the arrival time;
2.  $a_i$ , the amplitude;
3.  $\nu_i$ , the local frequency;
4.  $\phi_i$ , the azimuth in the horizontal plane;
5.  $\psi_i$ , the angle of incidence to the vertical;
6.  $c_i$ , the P or S type of the arrival.

An assumption tree is used for further identification (Tong and Kennett, 1996). In analogy to rules of thumb employed by expert seismologists a heuristic method is suggested. The phase identification follows the assumption tree given in Fig. 16.24, starting with key phases like P and S first arrivals. At each level of the assumption tree, a set of assumptions about a single factor is tested.

**Fig. 16.24** Assumption tree for seismic event classification hierarchy (after Tong and Kennett, 1996).

At each node, the information of its parent node is gathered and includes extra information, starting with just the observed data. In case of contradictions, the branching associated with the current node is terminated. Otherwise the branching process continues with the evaluation of further hypothesis. When no further assumptions are to be tested, a solution is represented based on a set of hypothesis describing the data.

**Tab. 16.5** Ranges of travel time differences between P and S phases for different epicentral distances for the heuristic method proposed by Tong and Kennett (1996).

| P-S Identity           | Time Interval Range [min] | Distance Range [ $^{\circ}$ ] |
|------------------------|---------------------------|-------------------------------|
| P-S                    | 2.18-10.43                | 12-85                         |
| P-SKS                  | 9.37-10.65                | 82-99                         |
| P <sub>diff</sub> -SKS | 9.39-10.69                | 100-129                       |
| PP-SKS                 | 3.96-7.22                 | 82-129                        |
| PP-PS                  | 9.20-10.14                | 104-125                       |
| PKP-SKS                | 5.84-7.21                 | 114-143                       |
| PKP-SKKS               | 7.97-12.66                | 126-180                       |
| PKP-SS                 | 20.05-27.66               | 136-180                       |
| PKIKP-PKS              | 3.35-3.60                 | 126-141                       |

### 16.5.3 Post-picking and outlier detection

As mentioned before, even the most sophisticated automated algorithms introduce, to some degree, erroneous picks. Phase misinterpretation as shown in Fig. 16.18 or overestimated pick uncertainties are usually inevitable. In the following, we present tools to detect outliers in post-picking procedures.

Most commonly, erroneous picks are identified by large residuals in the event location routine. Frequently applied location routines like HYPOINVERSE (Klein, 2002) or

HYPOSAT (Schweitzer, 2001) are able to exploit additional information like phase names, uncertainty estimates, and other phase properties such as polarization angles in order to identify inconsistent picks. Some of these routines automatically down weight observations associated with large residual. Although it is a common practice, we point out that the velocity model used for location biases residual weights. Therefore, residual weights from location routines should never replace the observation weights assigned by the picker. Otherwise, correct picks might be down weighted due to an insufficient velocity model and might be useless for tomographic studies.

Furthermore, the presence of few outlier picks can have a significant influence on the hypocenter solution derived by traditional least-square approaches. Beamforming techniques as described e.g. by Pinsky (2006) or the Equal Differential Time (EDT) formulation implemented in the NonLinLoc location routine of Lomax et al. (2000) yield very robust hypocenter solutions even in the presence of outliers and may therefore also improve the detection of false picks. In practice, automatic picks associated with large residual are usually flagged in the location routine and might be reviewed by the network analyst.

Identifying outliers in the location routine requires the presence of an appropriate velocity model of the study area. Since automatic pickers are increasingly used to derive such models, simultaneous inversion of hypocenters and seismic velocities have to be performed to detect outlier picks. Such iterative inversion procedures are proposed e.g. by Diehl et al. (2009a). Finally, Wadati diagrams as described, for example, by Kisslinger and Engdahl (1973) or Maurer and Kradolfer (1996) are used to identify mispicked S wave arrivals, independent of the P and S wave velocity structure.

## **16.6 Practical considerations: implementation, calibration, and pitfalls of automatic detection and picking procedures**

Implementation and realization of automatic detection and picking procedures depend on the application purpose and the available data. Commonly, these automatic procedures are used in permanent seismic weak-motion networks to detect and locate events in real or near-real time and the focus is on low detection thresholds in order to generate earthquake catalogs as complete as possible. However, increasingly, such automatic procedures are nowadays also applied on records from very dense strong-motion accelerometer networks such as the Japanese K- and KiK nets (see Chapter 8, sub-section 8.7.3). They trigger events on higher detection thresholds. Therefore, these records are, as compared to very sensitive weak-motion records, less or not at all effected by the preceding microseismic noise. Nevertheless, sophisticated algorithms are used to identify phase onset times. E.g. Akazawa (2004) uses a combination of STA/LTA ratios of a cumulative envelope function and the AR-AIC algorithm to exploit strong motion records of the K-, KiK-, and the CEORKA (Committee of Earthquake Observation and Research in the Kansai Area) networks. In any event, the calculated automatic locations have to be robust and available within minutes after an event. Finally, network applications have to handle signals in a broad frequency range in order to detect and pick events from local to teleseismic distances.

A second class of applications is the use within the increasing number of temporary deployments (aftershock deployments, temporary field deployments, etc.), which generate huge data volumes. Furthermore, the number of available analysts is usually limited. Focus for this class of applications is variable, but usually includes high detection rates for local to

regional events. Computing time of detection, picking, and location is less crucial and teleseismic events are already identified by global bulletins.

Finally, application of “re-picking” studies become increasingly important, in which automatic algorithms are used to improve consistency and quality of existing network picks, or to merge picks of several networks. For this class, event detection is usually not necessary and focus is on high-quality picks. Preliminary locations in combination with available earth models can be used to predict windows of first and later arriving phases. If arrival times are required for high-resolution tomography, consistency of picks is favored over hit-rate of algorithms, since completeness is less relevant. Numbers of erroneous picks, however, have to be as small as possible since residuals of outliers in the post-picking detection might be of the same order than residuals due to velocity anomalies. A suite of iterative detection stages might precede this “high-quality” application.

No matter which algorithm is chosen, automatic procedures have to be calibrated and tested with any new data set, i.e. the parameters of the algorithms have to be adjusted and optimized towards the application purpose. In this section we describe calibration and test procedures for automatic pickers. Furthermore, the pre-processing and quality of waveform data is crucial for reliable automatic procedures. Therefore, common pitfalls related to waveform filters and waveform quality are discussed at the end of this section.

### **16.6.1 Calibration and test of automatic pickers**

Typically, calibration and test of automatic algorithms is achieved by comparison with a set of representative manually picked onset readings (e.g. Baer and Kradolfer 1987; Sleeman and van Eck 1999; Di Stefano et al. 2006). A common practice is the use of network picks (i.e. arrival times routinely picked by network analysts on a day-to-day basis) as reference for the automatic algorithms. These network picks, however, are usually not appropriate to serve as reference picks, because they yield a high level of noise due to mispicks and other inconsistencies, particularly in error assessment. Reference arrival times for calibration and meaningful tests of automatic algorithms have to be picked consistently. In addition, reference picks have to be provided with a consistent measure of uncertainty in terms of phase timing (see sub-section 16.5.1) and phase identification (see sub-section 16.5.2). Seismograms with no identifiable phases (e.g. due to low signal-to-noise ratio) have to be flagged, in order to test the automatic picker’s ability to reject low-quality signals. Finally, consistent use of waveform filters during reference picking is necessary to avoid biases between automatic and manual picks. Additional use of theoretical arrival times, component rotation and tools like polarization analysis might be necessary for reliable reference picking of S waves. A detailed description on reference picking can be found in Diehl et al. (2009a) and IS 11.4. The set of reference picks should be divided in two subsets. The first subset is used to calibrate the algorithm and subsequently, the calibrated algorithm is tested with the other half.

Calibration of algorithms (i.e. adjustment of parameters) is usually accomplished by trial-and-error methods. Parameters are adjusted in order to minimize the difference between automatic and reference picks. As mentioned earlier, the trade-off between hit rate, precision, and number of outliers depends on the application purpose. Additional information on automatic quality assessment can be included in the performance evaluation using a matrix representation as suggested by Di Stefano et al. (2006). The quality assessment of the automatic picker must be tuned to get quality classes, which are similar or even equal to the

manually derived onset weights. Because automated algorithms usually evaluate the weighting classes differently than the analysts (e.g. using SNR determined from the seismogram and/or the CF, slope of CF, combination of both, etc.), the aim of exactly matching manual and automatic weighting classes is hard to achieve. In general, a sufficient calibration is obtained if the automatic picker upgrades only a very few low-quality reference picks to top quality classes and the majority of the high-quality reference picks is correctly classified as top quality. If only high-quality picks are requested (e.g. high-resolution tomography or high-precision relocation studies), the automatic quality assessment must be tuned such that none of the lowest-quality picks is classified as highest-quality (e.g. Di Stefano et al. 2006; Diehl et al. 2009a). As a consequence, a lot of intermediate-quality picks are rejected, resulting in an incomplete but high-quality set of arrival times. In contrast, for coarse location purposes the picker must be trained towards increased hit rate of intermediate-onset readings to assure a sufficient number of observations and azimuthal coverage for robust event location. Finally, to ensure that the calibrated algorithm is appropriate for the entire data set (and not just for the subset used for calibration), it should be tested with a second subset of reference picks as described earlier.

Sophisticated packages like MannekenPix (Aldersons 2004) or the algorithm proposed by Nippres et al. (2010) make use of data adaptive calibration in order to improve performance of picking and quality assessment and to avoid tedious trial-and-error procedures. Parameters are determined from the reference picks by an inverse technique based on pattern recognition. In practice, most automatic algorithms require a minimum of parameter search to determine the optimized choice of essential (data depending) picking parameters, such as search-window definitions or waveform filters.

### **16.6.2 Pre-processing: waveform filters**

The estimation of arrival times depends on the chosen frequency band and differences in arrival times determined in different frequency ranges may be in the order of several seconds. The effect of waveform filters on the arrival time picking is illustrated in Fig. 16.25. On the other hand, application of filters often enhances the signal-to-noise ratio. High-pass filters are used to remove microseismic noise and low-pass filters are commonly used to eliminate anthropogenic noise. To minimize the bias introduced by inconsistent application of filters, only one frequency band should be used for picking. Filters should be of zero-phase-type to avoid systematic time shifts. For a consistent analysis of arrival times, filters used for reference picking should be identical with filters used during automatic picking.

In practice, however, the use of one fixed frequency band for picking is often inapplicable, especially when dealing with data of earthquakes from wide distance and magnitude ranges. Differences in frequency content of seismic signals are mainly caused by the source processes and to minor extend by phase shifts due to wave propagation (attenuation, finite frequency effects). Finite rupture processes of large earthquakes lead, especially in the near field, to very complex signals, dominated by low frequencies. Simpler signals are expected for the point-source characteristics of small and moderate magnitudes. Frequency content varies for local Pg, regional Pn, and teleseismic mantle or core phases and might even change with focal depth. Finally, the noise characteristic can be station dependant, especially for regional and global networks.

To account for the diversity in signal and noise characteristic, data adaptive filters like the Wiener filter can be used to enhance the signal-to-noise ratio of seismic data. The Wiener filter, as implemented in MannekenPix (Aldersons 2004), measures the power spectrum in two windows:  $P_N(f)$  is determined from a window containing background noise and  $P_{SN}(f)$  is measured in a window containing signal and noise. As described by Aldersons (2004) the Wiener filter can be approximated by:

$$W(f) \approx \frac{P_{SN}(f) - P_N(f)}{P_{SN}(f)}$$

The obvious advantage of the Wiener filter is that it affects only frequencies associated with the background noise. In the ideal case, the filter does not modify the signal part, in contrast to traditional high-, low-, or band-pass filters. This assumption, however, is only valid if the signal-spectrum does not overlap with the noise-spectrum. Implementations like in MannekenPix require *a priori* information on the approximate position of the onset (initial pick from predicted arrival time or some sort of preliminary pick) to properly setup the noise and signal+noise windows. A gap between both windows has to account for the uncertainty of the initial picks and the length of the windows have to be appropriate for the expected noise and signal frequencies. Improper choice of these parameters might introduce additional instabilities to the Wiener filter.

**Fig. 16.25** Unfiltered (black) and filtered (red) local event waveform of a broadband record (Guralp CMG, 60 s – 50 Hz) using a 3<sup>rd</sup> order butterworth bandpass (2-10 Hz) and corresponding manual (blue vertical line) and automatic picks (green vertical line) indicating the effect of different filtering on P-onset determination. Note that in the more narrow-band high-frequency filtered record the amplitude of the first oscillations is strongly reduced, the negative first motion, still distinct in the broadband record, no longer recognizable and the phase of the oscillations significantly shifted. The reasons for these signal distortions due to filtering are discussed in Chapter 4.

A simple data adaptive filter is proposed by Tong (1995), who determines the dominant frequency  $f_n$  of the background noise and defines low- and high-pass filters based on  $f_n$ . Picking on multiple (fixed) frequency bands as well as filters depending on epicentral distance or station site might be used to account for differences in the signal and noise characteristics.

### 16.6.3 Pre-processing: waveform quality

The quality of available waveform data is crucial for reliable and robust automatic detection and picking procedures. “Glitches” present in time series can generate a high number of false picks and have to be identified and, if possible, removed prior to the picking. Common glitches are spikes, abrupt offsets in amplitudes (caused by data gaps or sensor re-centering), clipped amplitudes, and precursory oscillations prior to impulsive onsets (caused by instrumental acausal anti-alias filters). If filters are applied to these glitches and if they occur close to a seismic event, they are indistinguishable from real signals for most automatic algorithms. Spikes in the data can be identified and removed by running average routines as implemented e.g. in the SAC software. Clipped amplitudes usually inhibit reliable S wave detection and therefore, clipped seismograms have to be identified and removed prior to automatic S picking as described e.g. by Diehl et al. 2009b. Effects of acausal anti-alias filters can be removed by an inverse filtering process described e.g. in Scherbaum (2001) or may be minimized by application of certain low-pass filters. Problems with data quality are usually specific to networks and procedures to detect and remove them have to be developed and adjusted from case to case. Therefore, tests with reference data have to be used to identify these problems and to develop and calibrate tools to remove them.

## Appendix

### Introduction

The alphabetical listing below gives in bold letters the names of **Programs** or complementary educational **Files** (animations, PPTs, pdfs), mentioned in the NMSOP-2 texts, that are offered for free download.

Program folders may contain several files, such as program descriptions/manuals, sub-programs, source codes and executable files. Files or folders that are hyperlinked with the respective program archive administered by the GFZ library are written in **bold blue letters**. Authors of the programs and downloadable files have direct access via password (to be requested from the GFZ Chief Librarian, Mr. Roland Bertelmann, [rab@gfz-potsdam.de](mailto:rab@gfz-potsdam.de)) for uploading new or revised/upgraded programs or file versions.

Interested users may **download** the respective **Programs** or **Files** by left mouse click on the respective folder or file name typed in **bold blue letters**. **Animation and PPT files**, when typed in **bold blue letters**, may also **be activated** directly from the related NMSOP-2 texts via left mouse click on the file names.

Files that are part of a folder package are also listed below in alphabetical order, yet typed in **bold black letters**. They are downloaded together with the hyperlinked **folders in bold blue**.

**Note:** If animations are running for your purpose or comprehension too fast or too slow then catch the running movie cursor with a left mouse button click, hold the button pressed and then control the movie speed according to the time you need to read the texts and to follow the movie.

### Programs

EX 11.1)

[gfz\\_ma\\_chile2010 rupture](#) (Animation of the seismic energy release in space and time  
during the 2010 Mw8.8 Chile earthquake; Author: Yanlu Ma, GFZ Potsdam; see IS 1.1)

[optinet:ppt](#) (PPT tutorial, complementary to IS 8.7; Author: P. Bormann)

[ohrnberger\\_sumatra2004\\_rupture](#) (Animation of the seismic energy release in space and time during the 2004 Mw9.3 Sumatra-Andaman earthquake; Authors: M. Ohrnberger and F. Krueger, 2005; see IS 1.1)

[reference events](#) (data folder compiled by S. Wendt)

[ref\\_evt\\_00\\_05.tar.gz](#) (data file in folder [reference events](#) by S. Wendt)

[ref\\_evt\\_06\\_09.tar.gz](#) (data file in folder [reference events](#) by S. Wendt)

[ref\\_evt\\_94\\_99.tar.gz](#) (data file in folder [reference events](#) by S. Wendt)

[s1.tar](#) (waveform data files for onset picking in the SPEAR project by C. Zeiler, see IS 11.5)

[s2.tar](#) (waveform data files for onset picking in the SPEAR project by C. Zeiler, see IS 11.5)

[wendt\\_fiji\\_qt](#) (Animation of ray propagation; Author: S. Wendt; see IS 11.3)

[wendt\\_hindukush\\_qt](#) (Animation; mantle and depth phases; Author: S. Wendt; see IS 11.3)

[wendt\\_india\\_qt](#) (Animation; rays of mantle and core phases; Author: S. Wendt; see IS 11.3)

[wendt\\_newbritain\\_qt](#) (Animation; rarely observed multiple core phases; Author: S. Wendt)

[wendt\\_nz\\_qt](#) (Animation; teleseismic seismic phases and wavefronts; Author: S. Wendt)

[wendt\\_peru\\_qt](#) (Animation, rarely observed core phases; Author: S. Wendt; see IS 11.3)

[wendt\\_russlchina\\_qt](#) (Animation; depth and other phases; Author: S. Wendt; see IS 11.3)

[wendt\\_slovenia\\_qt](#) (Animation; regional seismic wavefronts; Author: S. Wendt; see IS 11.3)

[wendt\\_source\\_migra\\_around](#) (Animation with text on the 2- and 3-D viewing of the development of an earthquake swarm in space and time in its relation to dominating regional tectonic trends; Author: S. Wendt; see IS 1.1).

[wendt\\_source\\_rad\\_pat](#) (Animation with text on the dependence of source directivity and radiation pattern of P- and S- wave amplitudes on distance, strike, dip and rake angle for different types of source mechanism; Author: S. Wendt; see IS 1.1 and Chapter 3)

[wendt\\_vogtland1\\_qt](#) (Animation; local seismic wavefronts; Author: S. Wendt; see IS 11.3)

[wendt\\_vogtland2\\_qt](#) (Animation; local seismic wavefronts; Author: S. Wendt; see IS 11.3)

## Download programs and files

[wendt\\_waveprop\\_circles](#) (Animation with text on the P- and S-wave propagation from a local earthquake through a regional seismic network, the formation of the related travel-time curves and seismic records at the seismic stations, the determination of the epicentre by means of the circle and chort method and of the hypocenter depth by iterative reduction of the circle overshoot (Author: S. Wendt; see IS 1.1 and EX 11.1).

## Acronyms

|          |                                                                                                                                                                                                 |
|----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ETS      | episodic tremor and slip                                                                                                                                                                        |
| EX       | acronym for exercises in NMSOP                                                                                                                                                                  |
| FARM     | technique for data exchange                                                                                                                                                                     |
| FBA      | force-balance accelerometer                                                                                                                                                                     |
| FDSN     | Federation of Digital Broad-Band Seismograph Networks<br>( <a href="http://www.fdsn.org/">http://www.fdsn.org/</a> )                                                                            |
| FEC      | forward error-correction                                                                                                                                                                        |
| FEIS     | fast earthquake information system (see Chapter 9)                                                                                                                                              |
| FEMA     | Federal Emergency Management Agency (USA)<br>( <a href="http://www.fema.gov">http://www.fema.gov</a> )                                                                                          |
| FFT      | fast Fourier transformation                                                                                                                                                                     |
| FINES    | code for a small aperture array in southern Finland, originally:<br>FINESA: Finnish Experimental Seismic Array; later: FINESS –<br>Finnish Experimental Seismic System                          |
| FITESC   | field investigation team of the ESC                                                                                                                                                             |
| FIR      | finite impulse response filter, also named acausal- or zero-phase filter                                                                                                                        |
| f-k      | frequency-wavenumber (analysis)                                                                                                                                                                 |
| FM       | frequency modulated                                                                                                                                                                             |
| FOCMEC   | program for the determination of focal mechanisms (Chapter 3)                                                                                                                                   |
| PPFIT    | program for the determination of fault-plane solutions (Chapter 3)                                                                                                                              |
| FRF      | frequency response function                                                                                                                                                                     |
| FSNR     | frequency-based signal-to-noise-ratio                                                                                                                                                           |
| FTAN     | Frequency-time analysis (Chapter 14)                                                                                                                                                            |
| FTP      | fast transfer protocol                                                                                                                                                                          |
| FUNIMAR  | fast invariate case of the minimum Aikake information criterion (see<br>AIC and Chapter 16)                                                                                                     |
| FZ       | fault zone                                                                                                                                                                                      |
| GA       | genetic algorithm                                                                                                                                                                               |
| GBF      | generalized beam forming location algorithm developed at NORSAR<br>(see Chapter 9)                                                                                                              |
| GCF      | Guralp compressed format                                                                                                                                                                        |
| GCI      | Global Communication Infrastructure (see Chapter 17))                                                                                                                                           |
| GDSN     | Global Digital Seismographic Network (see GSN)                                                                                                                                                  |
| GEM      | Global Earthquake Model ( <a href="http://www.globalquakemodel.org/">http://www.globalquakemodel.org/</a> )                                                                                     |
| GEOFON   | GeoForschungsNetz (of broadband seismographs; run by the GFZ;<br><a href="http://geofon.gfz-potsdam.de">http://geofon.gfz-potsdam.de</a> )                                                      |
| GEOSCOPE | French program and station network for global seismological<br>investigations ( <a href="http://geoscope.ipgp.fr/">http://geoscope.ipgp.fr/</a> )                                               |
| GERES    | Code for a small aperture array in southern Germany, originally:<br>GERESS - German Experimental Seismic System (for weblink see<br>GRSN)                                                       |
| GFZ      | GeoForschungsZentrum Potsdam (Germany)<br>( <a href="http://www.gfz-potsdam.de/">http://www.gfz-potsdam.de/</a> )                                                                               |
| GIS      | geographical information system                                                                                                                                                                 |
| GIT      | generalized inversion technique (Chapter 14)                                                                                                                                                    |
| GLONAS   | Russian global (satellite-based) navigation system (as GPS)                                                                                                                                     |
| GPS      | US (satellite-based) global positioning system<br>( <a href="http://www.colorado.edu/geography/gcraft/notes/gps/gps_f.html">http://www.colorado.edu/geography/gcraft/notes/gps/gps_f.html</a> ) |
| G-R      | Gutenberg-Richter (magnitude-frequency relationship)                                                                                                                                            |
| GRF      | station code for the broadband array near Gräfenberg, Germany;<br>see weblink GRSN with array outlay and <a href="http://www.szgrf.bgr.de/">http://www.szgrf.bgr.de/</a>                        |

| INSAR  | interferometric (analysis of) synthetic aperture radar (images)                                                                                                                            |
| IP     | Internet protocol; combination of numbers which is associated with a computer in the Internet, for explicit identification of a computer                                                   |
| IPGP   | Institut de Physique du Globe de Paris<br>( <a href="http://www.ipgp.fr/index2.php?Largeur=1280">http://www.ipgp.fr/index2.php?Largeur=1280</a> )                                          |
| IRIS   | Incorporated Research Institutions for Seismology (USA)<br>( <a href="http://www.iris.edu/hq/">http://www.iris.edu/hq/</a> )                                                               |
| ISAM   | indexed sequential access method                                                                                                                                                           |
| ISC    | International Seismological Centre (Thatcham, UK)<br>( <a href="http://www.isc.ac.uk/">http://www.isc.ac.uk/</a> )                                                                         |
| ISN    | independent sub-network of the IMS (see Chapter 17)                                                                                                                                        |
| ISS    | International Seismological Summary (see Chapters 4, 41, and 88 in Lee et al., 2002).                                                                                                      |
| ISDN   | Integrated Services Digital Network                                                                                                                                                        |
| ISF    | IASPEI Seismic Format (Chapter 10);<br><a href="http://www.isc.ac.uk/standards/isf">http://www.isc.ac.uk/standards/isf</a>                                                                 |
| ISOP   | International Seismic Observing Period (important international project proposed by IASPEI in the 1990s; only partially realized)                                                          |
| ITRF   | International Terrestrial Reference Frame (defined by a combination of VLBI, SLR, DORIS and GPS currently used to represent absolute coordinates for sub-centimeter geodetic measurements) |
| IUGG   | International Union of Geodesy and Geophysics<br>( <a href="http://www.iugg.org/">http://www.iugg.org/</a> )                                                                               |
| JB     | Joyner-Boore, JB distance is the distance to the nearest point on the surface projection of a fault rupture                                                                                |
| J-B    | Jeffrey-Bullen (travel-time curves or Earth model)                                                                                                                                         |
| JMA    | Japanese Meteorological Agency<br>( <a href="http://www.jma.go.jp/jma/indexe.html">http://www.jma.go.jp/jma/indexe.html</a> )                                                              |
| JPL    | Jet Propulsion Laboratory at Pasadena, California.                                                                                                                                         |
| KAPG   | former Commission of the Academies of Sciences of Socialistic Countries for Planetary Geophysical Research                                                                                 |
| KNMI   | The Royal Netherlands Meteorological Institute (for Research Seismology Division see: <a href="http://www.knmi.nl/research/seismology/">http://www.knmi.nl/research/seismology/</a> )      |
| LAB    | lithosphere-asthenosphere boundary                                                                                                                                                         |
| LASA   | Large Aperture Seismic Array (Montana, USA, in operation from 1965 to 1978)                                                                                                                |
| LF     | low frequency                                                                                                                                                                              |
| LFE    | low-frequency earthquakes                                                                                                                                                                  |
| LDEO   | Lamont-Doherty Earth Observatory, Palisades, N.Y., USA, formerly LDGO (see <a href="http://www.ldeo.columbia.edu">http://www.ldeo.columbia.edu</a> ),                                      |
| LDGO   | Lamont-Doherty Geological Observatory, Palisades, N.Y. USA                                                                                                                                 |
| LP     | stands for either low pass (filter) or long-period (seismographs)                                                                                                                          |
| LTA    | long-term average (of noise and/or signal amplitudes) (Chapter 9 and IS 8.1)                                                                                                               |
| LTI    | Linear time-invariant                                                                                                                                                                      |
| LVZ    | low-velocity zone                                                                                                                                                                          |
| Ma     | Mega annum; an abbreviation for million years ago                                                                                                                                          |

|                |                                                                                                                                                                         |
|----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $M_0$          | scalar seismic moment                                                                                                                                                   |
| mb             | seismic body-wave magnitude; determined from short-period P wave amplitude and period measurements                                                                      |
| mB             | seismic body-wave magnitude; determined from amplitude and period measurements on medium-period or broadband records of P, PP and S waves                               |
| MCS            | Mercalli-Cancani-Sieberg seismic intensity scale.                                                                                                                       |
| MCSP           | multi-channel seismic profiling                                                                                                                                         |
| MDA            | multiple discriminant analysis (Chapter 16)                                                                                                                             |
| MDP            | macroseismic data point                                                                                                                                                 |
| Me             | energy magnitude                                                                                                                                                        |
| MEDNET         | MEDiterranean NETwork ( <a href="http://www.mednet.ingrm.it/">http://www.mednet.ingrm.it/</a> )                                                                         |
| MEMS           | micro-electromechanical systems                                                                                                                                         |
| miniSEED       | SEED format without any of the associated control header information                                                                                                    |
| $M_l$ or $M_L$ | local magnitude (according to the original definition by Richter (1935))                                                                                                |
| MLM            | maximum-likelihood method                                                                                                                                               |
| $M_m$          | magnitude derived from observation of mantle surface waves                                                                                                              |
| MMI            | modified Mercalli intensity                                                                                                                                             |
| MM56           | Modified Mercalli Scale of 1956                                                                                                                                         |
| $M_{max}$      | maximum magnitude                                                                                                                                                       |
| $M_{ms}$       | magnitude derived from macroseismic intensity observation                                                                                                               |
| MOHO (Moho)    | abbreviation for the Mohorovičić-discontinuity (boundary between the Earth's crust and mantle)                                                                          |
| MP events      | multi-phase events (observed at volcanoes)                                                                                                                              |
| MPX            | program for automated phase picking                                                                                                                                     |
| $M_s$          | surface-wave magnitude                                                                                                                                                  |
| MSB            | most significant bit                                                                                                                                                    |
| MSEED          | mini-SEED (data format)                                                                                                                                                 |
| MSK            | macroseismic intensity scale according to Medvedev, Sponheuer and Karnik                                                                                                |
| MSOP           | Manual of Seismological Observatory Practice (1979 edition) (see <a href="http://www.iaspei.org/projects/NMSOP.html">http://www.iaspei.org/projects/NMSOP.html</a> )    |
| MSPAC          | modified SPAC method (see SPAC and Bettig et al., 2001)                                                                                                                 |
| $M_t$          | tsunami magnitude                                                                                                                                                       |
| MUSIC          | multiple signal classification (see Chapter 9)                                                                                                                          |
| $M_w$          | seismic moment magnitude according to Kanamori (1977)                                                                                                                   |
| NASA           | National Aeronautics and Space Administration (USA) ( <a href="http://www.nasa.gov/">http://www.nasa.gov/</a> )                                                         |
| NCSN           | Northern California Seismic Network (USA) ( <a href="http://quake.geo.berkeley.edu/ncsn/ncsn.overview.html">http://quake.geo.berkeley.edu/ncsn/ncsn.overview.html</a> ) |
| NDC            | national data centers (in the framework of the PTS/CTBTO)                                                                                                               |
| NDPC           | NORSAR data processing center                                                                                                                                           |
| NEHRP          | National Earthquake Hazards Reduction Program of the United States                                                                                                      |
| NEIC           | National Earthquake Information Center of the USGS; acts as WDC for earthquake data ( <a href="http://neic.usgs.gov/">http://neic.usgs.gov/</a> )                       |
| NEIS           | U.S. Geological Survey National Earthquake Information Service (no longer used abbreviation)                                                                            |
| NERC           | Natural Environment Research Council (USA) ( <a href="http://www.nerc.ac.uk/">http://www.nerc.ac.uk/</a> )                                                              |
| NERIES         | Network of Research Infrastructures for European Seismology                                                                                                             |

## Acronyms

|         |                                                                                                                                                                                                                                  |
|---------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| NEWS    | NORSAR's earthquake warning system (see Chapter 9)                                                                                                                                                                               |
| NetDC   | Networked Data Center Protocol (see Chapter 10)<br>( <a href="http://www.iris.washington.edu/manuals/netdc/netdcuser.htm">http://www.iris.washington.edu/manuals/netdc/netdcuser.htm</a> )                                       |
| NGA     | next generation attenuation                                                                                                                                                                                                      |
| NGNM    | New Global Noise Model (see section 4.1.2)                                                                                                                                                                                       |
| NHNM    | New High-Noise Model (see section 4.1.2)                                                                                                                                                                                         |
| NHV     | seismic noise spectral ratio between horizontal-to-vertical component (Chapter 14)                                                                                                                                               |
| NMSOP   | New Manual of Seismological Observatory Practice (2002, 2009 and 2011-12 editions; see <a href="http://nmsop.gfz-potsdam.de">http://nmsop.gfz-potsdam.de</a> )                                                                   |
| NNSN    | Norwegian National Seismic Network<br>( <a href="http://www.geo.uib.no/seismo/naar-jorden-skjelver/index.php?topic=nnsn&amp;lang=es">http://www.geo.uib.no/seismo/naar-jorden-skjelver/index.php?topic=nnsn&amp;lang=es</a> )    |
| NOA     | since 1978 station code for the large aperture NORSAR array<br>( <a href="http://www.norsardata.no/NDC/stations/NOA/">http://www.norsardata.no/NDC/stations/NOA/</a> )                                                           |
| NOAA    | National Oceanic and Atmospheric Administration (USA)<br>( <a href="http://www.noaa.gov/">http://www.noaa.gov/</a> )                                                                                                             |
| NORES   | station code of a small aperture array in southern Norway, originally NORESS – Norwegian Experimental Seismic Station<br>( <a href="http://www.norsardata.no/NDC/stations/NRS/">http://www.norsardata.no/NDC/stations/NRS/</a> ) |
| NORSAR  | Norwegian seismological institute, originally used for the large aperture seismic array in southern Norway (from NORwegian Seismic ARray) ( <a href="http://www.norsar.no/">http://www.norsar.no/</a> )                          |
| NPEF    | noise prediction-error filter                                                                                                                                                                                                    |
| NSF     | National Science Foundation (USA)                                                                                                                                                                                                |
| NTS     | Nevada Test Site ( <a href="http://www.nv.doe.gov/main.aspx">http://www.nv.doe.gov/main.aspx</a> )                                                                                                                               |
| OBS     | ocean-bottom seismograph (see sub-chapter 7.5 of Chapter 7)                                                                                                                                                                      |
| OBH     | ocean-bottom hydrophone                                                                                                                                                                                                          |
| ODC     | ORFEUS Data Center (De Bilt, Netherlands)                                                                                                                                                                                        |
| ODP     | Ocean Drilling Program (1983-2003)                                                                                                                                                                                               |
| ORFEUS  | Observatories and Research Facilities for European Seismology (De Bilt, Netherlands; <a href="http://www.orfeus-eu.org/">http://www.orfeus-eu.org/</a> )                                                                         |
| OSI     | on-site inspection capabilities (of the PTS/CTBTO)                                                                                                                                                                               |
| OT      | origin time                                                                                                                                                                                                                      |
| PACF    | partial auto-correlation function                                                                                                                                                                                                |
| PASSCAL | Program for Array Seismic Studies of the Continental Lithosphere (see: <a href="http://www.passcal.nmt.edu/content/usarray">http://www.passcal.nmt.edu/content/usarray</a> )                                                     |
| PCEQ    | pulse-coded earthquake data format (Chapter 10)                                                                                                                                                                                  |
| PD      | program descriptions in NMSOP                                                                                                                                                                                                    |
| PDE     | preliminary determination of epicenters (NEIC event data reports)                                                                                                                                                                |
| PDF     | probability density function                                                                                                                                                                                                     |
| PDR-2   | local format in use at individual stations and networks                                                                                                                                                                          |
| PGA     | peak ground acceleration                                                                                                                                                                                                         |
| PGD     | peak ground displacement                                                                                                                                                                                                         |
| PGV     | peak ground velocity                                                                                                                                                                                                             |
| PIDC    | the former Prototype International Data Center (USA); many PIDC products are still available at the DTRA Verification Data Base ( <a href="http://www.rdss.info/">http://www.rdss.info/</a> )                                    |
| PITSA   | programmable interactive toolbox for seismological analysis                                                                                                                                                                      |
| PMCC    | progressive multichannel cross-correlation method                                                                                                                                                                                |
| PML     | probable maximum loss                                                                                                                                                                                                            |

|            |                                                                                                                                                                                                                                        |
|------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| POSEIDON   | Pacific Orient Seismic Digital Observation Network (Japanese seismic network for global seismological studies which includes OBS sites)                                                                                                |
| PREM       | Preliminary Reference Earth Model (see DS 2.1)                                                                                                                                                                                         |
| PREPROC    | program for preprocessing of digital seismic data                                                                                                                                                                                      |
| PSA        | pseudo-spectral acceleration                                                                                                                                                                                                           |
| PSD        | power spectral density                                                                                                                                                                                                                 |
| PSHA       | probabilistic seismic hazard assessment                                                                                                                                                                                                |
| PSRV       | pseudo relative velocity response spectrum                                                                                                                                                                                             |
| PTS        | Preparatory Technical Secretary of the Preparation Commission of the CTBTO in Vienna, Austria; organization running the IMS and IDC before the CTBT is coming into force                                                               |
| PVC        | Poly-Vinyl-Chloride                                                                                                                                                                                                                    |
| QED        | quick epicenter determinations (NEIC event data reports)                                                                                                                                                                               |
| Q          | quality factor; Q is inverse proportional to the attenuation of seismic waves, i.e., to the relative loss of energy per wave cycle                                                                                                     |
| RASA       | radionuclide aerosol sampler/analyzer (see Chapter 17)                                                                                                                                                                                 |
| RBW        | relative bandwidth                                                                                                                                                                                                                     |
| RC         | resistivity-capacity (electric circuit, filter, element etc.)                                                                                                                                                                          |
| RDBMS      | relational data base management system (see Chapter 17)                                                                                                                                                                                |
| rdseed     | SEED-reading program                                                                                                                                                                                                                   |
| RDSS       | former Research and Development Support System (at the CMR, USA), now integrated in the DTRA Verification Data Base ( <a href="http://www.rdss.info/">http://www.rdss.info/</a> )                                                      |
| REB        | reviewed event bulletin                                                                                                                                                                                                                |
| REDB       | reference event data base (of the IDC)                                                                                                                                                                                                 |
| Reftek     | Refraction Technology Inc.<br>( <a href="http://www.reftek.com/products/accelerometers-147-01.html">http://www.reftek.com/products/accelerometers-147-01.html</a> )                                                                    |
| RF         | radio frequency or Rossi-Forel intensity scale                                                                                                                                                                                         |
| RMS or rms | root mean square                                                                                                                                                                                                                       |
| ROSINE     | resolution of site response issues in the Northridge earthquake                                                                                                                                                                        |
| ROV        | remotely operated vehicle (see <i>Glossary</i> for reference)                                                                                                                                                                          |
| RSAM       | real-time seismic amplitude measurement                                                                                                                                                                                                |
| RSM        | reference site method (Chapter 14)                                                                                                                                                                                                     |
| RSTN       | remote seismic telemetered network                                                                                                                                                                                                     |
| SA         | sSpectral acceleration                                                                                                                                                                                                                 |
| SAC        | seismic analysis code (format used in standard analysis software)                                                                                                                                                                      |
| SAP        | signal attribute processing (s. Chapter 9, section 9.13.3)                                                                                                                                                                             |
| SAR        | successive approximation register<br><b>Also:</b> synthetic aperture radar (see <i>Glossary</i> for reference)                                                                                                                         |
| SAR-ADC    | Successive approximation analog-to-digital converter                                                                                                                                                                                   |
| SASCs      | slowness and azimuth station corrections (see Chapter 17)                                                                                                                                                                              |
| SCEC       | Southern California Earthquake Center<br>( <a href="http://www.scec.org/">http://www.scec.org/</a> )                                                                                                                                   |
| SCRs       | stable continental regions                                                                                                                                                                                                             |
| SCSI       | small computer system interface                                                                                                                                                                                                        |
| SCSN       | Southern California Seismic Network<br>( <a href="http://www.trinet.org/scsn/scsn.html">http://www.trinet.org/scsn/scsn.html</a> )                                                                                                     |
| SEB        | standard event bulletin (of the PIDC)                                                                                                                                                                                                  |
| SEED       | standard for the exchange of earthquake data (format designed for data exchange and archiving (for download the SEED manual see: <a href="http://www.iris.edu/manuals/SEED_chpt1.htm">http://www.iris.edu/manuals/SEED_chpt1.htm</a> ) |

## Acronyms

|                  |                                                                                                                                                                                                                                                                |
|------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| SEEDlink         | program package to exchange SEED data via Internet                                                                                                                                                                                                             |
| SEG Y            | data format                                                                                                                                                                                                                                                    |
| SEISAN           | Seismogram Analysis Software (manual and software can be downloaded from <a href="http://ftp.geo.uib.no/pub/seismo/SOFTWARE/SEISAN/">http://ftp.geo.uib.no/pub/seismo/SOFTWARE/SEISAN/</a> )                                                                   |
| SEL3             | standard event list 3; the final fully automatic bulletin of the IDC (PTS/CTBTO)                                                                                                                                                                               |
| SESAME           | Site Effects uSing AMBient Excitations; a European Union project (also the name of a project producing a unified hazard model for the Euro-Mediterranean region: <a href="http://www.ija.csic.es/gt/earthquakes/">http://www.ija.csic.es/gt/earthquakes/</a> ) |
| SGM              | strong ground motion                                                                                                                                                                                                                                           |
| SH               | Seismic Handler (data analysis program), command-line version                                                                                                                                                                                                  |
| SHI              | seismic hydroacoustic and infrasonic (data products see IS 10.3)                                                                                                                                                                                               |
| SHM              | Seismic Handler (data analysis program), motif version (see <a href="http://seismic-handler.org/portal">http://seismic-handler.org/portal</a> )                                                                                                                |
| SI               | Système International d'Unités (international system of standard units)                                                                                                                                                                                        |
| SKD              | classical medium- to long-period (in Russian: Dlinnoperiodnij) displacement-proportional seismograph constructed by D. P. Kirnos                                                                                                                               |
| SNR or S/N ratio | signal-to-noise ratio (see sub-chapters 4.4 and 9.6)                                                                                                                                                                                                           |
| SOFAR            | sound fixing and ranging                                                                                                                                                                                                                                       |
| SP               | short-period                                                                                                                                                                                                                                                   |
| SPAC             | spatial auto-correlation method, after Aki (1957) (Chapter 14)                                                                                                                                                                                                 |
| SPITS            | code for a small aperture array on Spitsbergen (Svalbard Archipelago)                                                                                                                                                                                          |
| SPT              | split-barrel sampling; also acronym for the Semipalatinsk test site in Kazakhstan                                                                                                                                                                              |
| SRL              | satellite laser ranging                                                                                                                                                                                                                                        |
| SRO              | Seismic Research Observatory (in a global USA network) using very specific 20 s bandpass and 6 s noise notch filtered LP records. For data and links see NMSOP-2 <i>Glossary</i> , Chapter 11, DS 11.2 and 11.3                                                |
| SS-1/SSR-1       | Kinematics "Ranger" seismometer and data logger, respectively                                                                                                                                                                                                  |
| SSA              | Seismological Society of America ( <a href="http://www.seismosoc.org/">http://www.seismosoc.org/</a> )                                                                                                                                                         |
| SSAM             | spectral seismic amplitude measurement                                                                                                                                                                                                                         |
| SSR              | standard spectral ratio method (Chapter 14)                                                                                                                                                                                                                    |
| SSSC             | source specific station correction (see Chapter 17)                                                                                                                                                                                                            |
| SSZ              | seismic source zone                                                                                                                                                                                                                                            |
| STA              | Short-term average (in a trigger algorithm) (see Chapter 9 and IS 8.1)                                                                                                                                                                                         |
| STA/LTA          | ratio of short-term to long-term average (trigger algorithm) (see IS 8.1 and Chapters 8 and 9)                                                                                                                                                                 |
| STA2             | sStation line in parameter data format (Chapter 10)                                                                                                                                                                                                            |
| StaPro           | station processing (see Chapter 17)                                                                                                                                                                                                                            |
| STEIM1 or 2      | Algorithms proposed by J. M. Steim for data compression                                                                                                                                                                                                        |
| STS1 or STS2     | Streckeisen seismometers, type 1 and 2, resp. (see DS 5.1)                                                                                                                                                                                                     |
| SUDS             | seismic unified data system (format designed for database systems)                                                                                                                                                                                             |
| SZGRF            | Seismological Central Observatory GRF (Gräfenberg, Germany; see <a href="http://www.szgrf.bgr.de/">http://www.szgrf.bgr.de/</a> )                                                                                                                              |
| TCP              | transmission control protocol                                                                                                                                                                                                                                  |
| TCP/IP           | transmission control protocol over Internet protocol                                                                                                                                                                                                           |
| TERRAScope       | very broadband seismographic network in Southern California                                                                                                                                                                                                    |
| TF               | telegraphic format                                                                                                                                                                                                                                             |
| THR              | SNR threshold used to define a detection                                                                                                                                                                                                                       |
| TR               | transient response                                                                                                                                                                                                                                             |

|          |                                                                                                                                |
|----------|--------------------------------------------------------------------------------------------------------------------------------|
| UHF      | ultra high-frequency range (around 450 MHz)                                                                                    |
| UHS      | uniform hazard spectrum                                                                                                        |
| ULF      | ultra low frequency (volcanic events with $f < 0.01$ Hz)                                                                       |
| ULP      | ultra long period                                                                                                              |
| UNE      | underground nuclear explosion                                                                                                  |
| UNESCO   | United Nations Educational, Scientific and Cultural Organization                                                               |
| UPS      | unbreakable power supply                                                                                                       |
| URL      | uniform resource locator; it is the address for locating a Web site, and consists of the protocol and the Internet address.    |
| URS      | uniform risk spectrum (actually the same as UHS)                                                                               |
| USESN    | United States Educational Seismology Network<br>( <a href="http://www.indiana.edu">http://www.indiana.edu</a> )                |
| USCGS    | United States Coast and Geodetic Survey                                                                                        |
| USGS     | United States Geological Survey ( <a href="http://www.usgs.gov/">http://www.usgs.gov/</a> )                                    |
| USNSN    | United States National Seismograph Network                                                                                     |
| UT       | universal time                                                                                                                 |
| UTC      | universal time coordinated; a time scale defined by the International Time Bureau and agreed upon by international convention. |
| VBB      | very broadband                                                                                                                 |
| VEI      | volcanic explosivity index                                                                                                     |
| VELEST   | program to derive 1-D seismic velocity models                                                                                  |
| VESPA    | velocity spectrum analysis                                                                                                     |
| VHF      | very-high frequency range (160-200 MHz)                                                                                        |
| VLBI     | very long baseline interferometry; uses radar frequencies around 9 GHz with wavelengths around 3 cm.                           |
| VLF      | very low frequency (volcanic events with $f \sim 0.01 - 1$ Hz)                                                                 |
| VLP      | very long period; in reference to the 27-second to 600-second band of seismic signals recorded by a modern GSN station.        |
| $v_p$    | P-wave velocity                                                                                                                |
| $v_s$    | S-wave velocity                                                                                                                |
| VSAT     | very small aperture terminals                                                                                                  |

## Acknowledgment

This second version of the NMSOP-2 Glossary is based on a very careful proof-reading, uniform formatting, and the spotting of missing links, references and entries by Ms. Dr. Myrto Pirli whom the authors owe great thanks. This tremendously eased the revision.

## 1 Introduction

**This is a preliminary glossary**, still under development, revision and amendment, also with respect to co-authorship. **Comments, corrections as well as proposals for complementary entries are highly welcome and should be sent to the editor, P. Bormann.** He has compiled the current version by combining, harmonizing, amending and sometimes correcting entries from three major earlier published glossaries of terms that are (see References):

- 1) frequently used in seismological observatory practice (glossary in the first edition of the IASPEI New Manual of Seismological Observatory Practice (NMSOP; Bormann, 2002 and 2009; see <http://nmsop.gfz-potsdam.de>);
- 2) of interest to earthquake and engineering seismologists (glossary compiled by Aki and Lee, 2003, for the International Handbook of Earthquake and Engineering Seismology (see Lee et al., 2003a);
- 3) now widely used in some rapidly developing new fields such as rotational seismology, (compiled by Lee, 2009).

The following glossary includes some 1,500 specialized terms. Not included were abbreviations and acronyms (with the exception of just a few that required more explanation). Acronyms have been added as an extra file to this Manual (see NMSOP-2 website cover page). Alphabetization is strictly letter-by-letter of the glossary terms (in bold face), ignoring hyphenation and space between words. Words included in parenthesis are also ignored in the alphabetization. Words which are written in *italics* in the explanatory text refer to other glossary terms for which more explanation is given elsewhere.

Terms in this glossary may be encountered when reading literature in seismological observatory practice, earthquake and engineering seismology and related fields. The purpose

of the glossary is to provide a short definition and/or a starting point for readers to learn more from cited references. Although rather extensive, this glossary is by no means complete. We attempt to give commonly used definitions, understandable also for non-specialists. But readers should realize that terms may be differently defined in some literature. We avoid giving mathematical formulas (except for a small number of cases). For key formulas in seismology we refer to Yehuda Ben-Zion (2003), as well as to Aki and Richards (2002 and 2009).

When compiling the above mentioned earlier main glossaries many earlier and widely scattered ones were consulted, such as glossaries published by the US Geological Survey (<http://www.usgs.gov/>), the Montana Bureau of Mines and Geology (<http://www.mbmng.mtech.edu/>), the International Data Center of the CTBTO (<http://www.ctbto.org>), and in addition several standard reference sources, including Aki and Richards (1980, 2002 and 2009), Ben-Menahem and Singh (2000), Bormann (2002), Clark (1966), EERI (1989), Hancock and Skinner (2000), Jackson (1997), James and James (1976), Lee and Stewart (1981), Lide (2002), Meyers (2002), Naeim (2001), Richter (1958), Runcorn (1967), Sigurdsson (2000), USGS Photo Glossary (2002), and Yeats *et al.* (1997). Some glossary terms and texts have also been contributed by chapter/section/entry authors of this Manual, amongst them J. Schweitzer, T. Diehl and L. Kueperkoch, as well as by authors of the International Handbook of Earthquake and Engineering Seismology (eds. Lee *et al.*, 2002 and 2003a) and of the BSSA special issue on rotational seismology (eds. Lee *et al.*, 2009, Lee *et al.*, 2009a, and 2009b), amongst them (for the latter) R. DeSalvo, J. R. Evans, E. F. Grekova, C. R. Hutt, H. Igel, C. A. Langston, B. Lantz, E. Majewski, R. Nigbor, J. Pujol, P. Spudich, R. Teisseyre, M. D. Trifunac, R. J. Twiss, and Z. Zembaty. Further terms and/or suggestions for revisions were provided by R. Adams, J. Anderson, J. Andrews, Y. Ben-Zion, M.G. Bonilla, D. Boore, K. Campbell, Ch. Chapman, C.B. Crouse, A. Curtis, A. Douglas, L. Esteva, B. Hall, D. Hill, B. Hutt, P. Irwin, K.-H. Jäckel, R. Jeanloz, P. Jennings, C. Kisslinger, O. Kulhanek, A. McGarr, M. Pirli, C. Prodehl, H. Sato, J. Savage, J. Schweitzer, A. Snoke, K. Suyehiro, B. Tilling, and S. Uyeda. More names may be added here with future entries.

Nevertheless, words of caution are required at this point. Although precise definitions are critical for fostering collaboration and reducing misunderstanding between different disciplines, there are no unique definitions of terms. Every scientific field seems to develop its own “jargon” that is sometimes difficult for outsiders to understand. Even within a given field, different authors often define technical terms differently, or a given term has different usage. This is particularly the case in rapidly developing new fields such as rotational seismology. Therefore, the compilers tried to use a usage that they judged to be “common”, or to indicate different meanings of the same term in different fields of Earth or technical sciences and sometimes by providing references to alternative and more specialized sources. With respect to rotational seismology these are especially the tutorials by Peters (2009), Pujol (2009), Teisseyre (2009), and Zembaty (2009b), and the review by Trifunac (2009). Evans *et al.* (2010) describe notation conventions for rotational seismology, while Grekova and Lee (2009) provide suggested readings in continuum mechanics (including elasticity theories), and earthquake seismology.

| <b>aa</b>             | A common type of <i>lava flow</i> composed of a jumble of <i>lava blocks</i> , with a rough, jagged, spiny, and generally clinkery or slaggy surface. Of Hawaiian origin, the term aa is applied also to similar lava flows at other volcanoes.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <b>acausal filter</b> | See <i>zero-phase filter</i> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| <b>acausal signal</b> | Output signal that exists also for times prior to the application of an input <i>signal</i> , a non-physical phenomenon of digital data processing.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <b>acceleration</b>   | When an object, e.g., a car, changes its speed from one speed to another, it is accelerating (moving faster) or decelerating (moving slower). This change in <i>velocity</i> is called acceleration. In seismology this term specifically means the rate of change of <i>ground motion</i> particle velocity per unit time when the ground is shaking due to an <i>earthquake</i> or another kind of <i>seismic source</i> process. The peak acceleration is the largest acceleration recorded by a particular station during an earthquake. In <i>strong-motion</i> seismology the ground acceleration is commonly expressed as a fraction or percentage of the acceleration due to gravity ( $g$ ) where $g = 981 \text{ cm/s}^2$ . For the strongest earthquakes ground accelerations of more than 1.5 $g$ have been recorded. Since the weight of an object, e.g., of a building, is equal to its mass multiplied by the gravity $g$ , the additional acceleration due to ground shaking causes an extra load. This extra load may exceed the strength of the building and may cause damage or collapse. |
| <b>accelerogram</b>   | A record (time history) of ground <i>acceleration</i> as a function of time produced by an <i>accelerograph</i> during a seismic event.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| <b>accelerograph</b>  | A compact, rugged, and relatively inexpensive <i>seismograph</i> designed to record the <i>signal</i> from an <i>accelerometer</i> , especially of strong ground shaking on ground or in structures, caused by nearby large earthquakes (see, e.g., Trifunac, 2009). Film used to be the most common analog recording medium. Modern accelerographs, however, record digitally with much larger <i>dynamic range</i> . Whereas a traditional <i>strong-motion</i> accelerograph begins recording when the motion exceeds a certain specified trigger level, at present, some <i>seismic networks</i> record acceleration within a large dynamic range continuously.                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <b>accelerometer</b>  | A sensor or <i>transducer</i> that converts <i>acceleration</i> of its base into an analog trace or electrical <i>signal</i> . The acceleration signal is normally obtained from the feedback current necessary to                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

maintain an *inertial sensor* at its mechanical zero point. As in a linear actuator the current is equal to the applied force, this current is proportional to the acceleration within the bandwidth limits of the feedback. Outside the band the acceleration can still be extracted from the position signal, normally through a complicated *transfer function*. Accelerometers may be enclosed within a self-contained *accelerograph*, but for studies of structural response they can be located remotely, with their signals being transmitted to a central recorder. Unless otherwise specified, an accelerometer measures translational acceleration. However, accelerometers are also sensitive to *rotational ground motions*.

**acceptable risk**

The probability associated with a social or economic consequence of an earthquake that is low enough (in comparison with other risks) to be judged acceptable by appropriate authorities. It is often used to represent a realistic basis for determining design requirements for engineered structures, or for taking certain social or economic actions. What kind and level of risk is considered to be acceptable by a society depends also on its socio-economic and political conditions.

**ACH method**

ACH stands for Aki, Christoffersson and Husebye (1977) who developed a method for determining the three-dimensional structure of the Earth using the *teleseismic* observations from a two-dimensional *seismic array*. The method was extended to the *local earthquake* data by Aki and Lee (1976). It opened one way to the research area now called “*seismic tomography*”.

**accretionary prism**

See *accretionary wedge*.

**accretionary wedge**

*Trench* sediments and volcanics that accumulate and deform where oceanic and continental *plates* collide. These sediments are scraped off the top of the downgoing oceanic crustal plate and are added as a generally wedge-shaped mass to the leading edge of the continental plate (Von Huene and Scholl, 1991; Duff, 1993; see *subduction* and *tectonic plates*).

**accuracy**

According to Bevington and Robinson (2003) a measure of how close the results of an experiment (observed values or values calculated from observations via model assumptions) come to the “true” value.

**acoustic emission**

A term in rock mechanics indicating *seismic wave* radiation from dynamic formation of a microcrack. Due to the small crack lengths, the *frequencies* of the radiated waves are in the kHz (acoustic or ultrasound) range.

|                               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

| <b>acoustic impedance</b>     | Product of wave propagation <i>velocity</i> $v$ and <i>density</i> $\rho$ of the medium in which the acoustic (or elastic seismic) waves propagate. See <i>seismic impedance</i> and <i>impedance contrast</i> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <b>active fault</b>           | A <i>fault</i> that is considered likely to undergo renewed movement within a period of concern to humans. Faults are commonly considered to be active if they have moved one or more times in the last 10,000 years, but they may also be considered active when assessing the hazard for very critical installations such as nuclear power plants even if movement has occurred in the last 500,000 years. Although faults that move in earthquakes today are active, not all active faults generate earthquakes - some are capable of moving aseismically (see <i>creep</i> , <i>silent earthquake</i> , <i>slow earthquake</i> ; also, e.g., Johnston and Linde, 2002). More precise attempts (usually unsatisfactory) have been made to define “active” faults for legal or regulatory purposes. See Yeats et al. (1997, p. 449). |
| <b>active margin</b>          | A continental margin that is also a <i>plate boundary</i> with earthquakes and/or volcanic activity.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <b>active tectonic regime</b> | A term that refers to regions where <i>tectonic deformation</i> is relatively large and earthquakes are relatively frequent, usually near <i>plate boundaries</i> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| <b>active tectonics</b>       | <i>Tectonic</i> movements that are expected to occur or have occurred within a time span of concern to society.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| <b>active volcano</b>         | By a widely used but poor definition, an active volcano is one that is erupting or has erupted one or more times in recorded history (see Decker and Decker, 1998). Active and potentially active (i.e., presently dormant) volcanoes occur in narrow belts that collectively comprise less than 1 percent of the Earth’s total surface (Simkin et al., 1994).                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| <b>aftershock</b>             | An earthquake occurring as a consequence of a larger earthquake (referred to as the <i>mainshock</i> ) at roughly the same location. Aftershocks are smaller than the mainshock and within 1-2 <i>fault lengths</i> distance from the mainshock fault. The sequence of such earthquakes following a larger one generally shows a regular decrease in the rate of occurrence, first discovered by Omori (1894), indicating a stress relaxation and redistribution process as the rocks accommodate to their new post-earthquake state. Aftershocks can continue over a period of weeks, months, or years, decreasing in frequency with time. In general, the larger the mainshock, the larger and more numerous the aftershocks, and the longer they will continue. See Utsu (2002b), and Eq. (7.4) in Ben-Zion (2003).                 |
| <b>afterslip</b>              | The increase in <i>displacement</i> on a <i>fault</i> by <i>creep</i> following a sudden <i>coseismic slip</i> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

|                                     |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|-------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>AIC</b>                          | <p>Akaike Information Criterion, applied in statistical modeling to get the most appropriate probability distribution that describes the observed data. Definition:</p> $AIC = -2 \cdot \max(L) + 2(p),$ <p>where <math>\max(L)</math> is the maximum likelihood function and <math>p</math> the number of free parameters. See Akaike (1970, 1971).</p>                                                                                                                                                                                                                                                                              |
| <b>airgun</b>                       | <p>A non-explosive <i>seismic source</i> normally used at sea. Compressed air (about 15 MPa) is fed into an air chamber of variable size (1-30 L) and is repetitively released into water to generate sound waves to be emitted.</p>                                                                                                                                                                                                                                                                                                                                                                                                  |
| <b>air-coupled surface wave</b>     | <p>Despite the great <i>density</i> contrast between air and ground, atmospheric <i>pressure</i> disturbances traveling over the Earth's surface can produce <i>surface waves</i> if the <i>phase velocity</i> is equal to the acoustic velocity in the air. Such a coupling with air has been observed for flexural waves in ice sheets floating on the ocean and for <i>Rayleigh waves</i> in ground with low-velocity surface layers. A simultaneous arrival of <i>air waves</i> and tidal disturbances was observed after the well known explosion of the volcano Krakatoa in 1883.</p>                                           |
| <b>air wave</b>                     | <p>Audible sounds or <i>infrasound</i> waves are sometimes generated by earthquakes; a <i>local earthquake</i> may sound like distant thunder, canon shots or the rumbling from a passing truck or tank on a bumpy road. Instrumental measurements show that these sounds arrive simultaneously with the first <i>P waves</i> (Hill et al., 1976). More long-<i>period</i> (seconds to hours) acoustic-gravity waves may also be excited by <i>great earthquakes</i>, as well as by volcanic explosions, meteorite falls, and nuclear blasts in the atmosphere. See Ben-Menahem and Singh (2000).</p>                                 |
| <b>Airy phase</b>                   | <p>Portions of dispersed wave trains associated with the maxima or minima of the <i>group velocity</i> as a function of <i>frequency</i>. The Airy function can be used for an approximate calculation of the <i>waveform</i>. Examples are continental <i>Rayleigh waves</i> at <i>periods</i> around 15 seconds, <i>mantle</i> Rayleigh waves at periods of 200 to 250 seconds, and <i>surface waves</i> of periods between some 6 and 10 seconds which travel across an ocean at a velocity near 1 km/sec. (see Fig. 2.10 of Chapter 2 in this Manual). See also Kulhanek (2002, p. 345), and Aki and Richards (1980, p. 256).</p> |
| <b>Akaike Information Criterion</b> | See <i>AIC</i> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| <b>aleatory uncertainty</b>         | <p>The uncertainty in <i>seismic hazard analysis</i> due to inherent random variability of the quantity being measured. Aleatory uncertainties cannot be reduced by refining modeling or analytical techniques. See <i>epistemic uncertainty</i>.</p>                                                                                                                                                                                                                                                                                                                                                                                 |

- aliasing** A serious error in the *analog-to-digital conversion*, pointed out by Blackman and Tukey (1958), that occurs when the sampling rate is less than twice the highest *frequency* (*Nyquist frequency*) contained in the *signal* to be digitized. A long *period* ghost which does not exist in the original *signal* may appear after digitization (see Chapter 6 of this Manual; also Aki and Richards, 1980, p. 576-579).
- alluvium** Loose gravel, sand, silt, or clay deposited by streams after the last ice age (see *Holocene*).
- Alpide belt** Mountain belt with frequent earthquakes that extends from the Mediterranean region, eastward through Turkey, Iran and northern India.
- altitude of ambiguity** The topographic relief (or error) required to create one fringe in an *interferogram*. The height of ambiguity is expressed in units of meters.
- ambient noise** See *noise*.
- amplification** (by seismograph) Most earthquakes are relatively small, in fact, so small that no one feels them. In order for seismologists to see the recording of the ground movement from smaller earthquakes, the recording has to be made larger. Modern *seismographs* are able to magnify the *ground motion*  $10^6$  times or even more, i.e., they are able to resolve ground motion *amplitudes* as small as the diameter of molecules or even atoms. The frequency-dependent amplification of a *seismograph* depends on the input spectrum of the *seismic signal*, the *eigenfrequency* and *attenuation* of the *seismic sensor* or *seismometer*, and of the filter parameters and gain of the *seismic recorder* (see Chapters 4 to 6 of this Manual).
- amplification** (by recording site) The term is also used to describe the increase in *amplitude* of *seismic waves* and/or levels of shaking at the site of recording or observation. Increase (or decrease) of amplitudes may be due to focusing (or defocusing) of seismic wave energy caused by the *geometry/heterogeneity* of the *velocity structure* of sediments and other rock formations, by basin subsurface topography, or by surface topography. Most *seismographs* are installed at a site on or near the surface with irregular topography and lithologic structures of heterogeneous material created by aeons of weathering, erosion, deposition and other geological processes. These complex near-surface structures also tend to amplify the amplitude of incident seismic waves (see *site effect* and *site response*). The degree of amplification is usually dependent on the *frequency* and thus on the *wavelength* of the *seismic signal* with respect to the linear dimensions of the surface and subsurface heterogeneities.

|                                           |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|-------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>amplitude</b>                          | The size of the wiggles on an earthquake recording; more general and correct in a physical sense the height of a wave-like disturbance - such as the seismic record trace (called <i>waveform</i> ) - from the medium (zero) level to its peak, respectively trough. When measured from peak to trough it is called double or “peak-to-peak” (more correct “peak-to-trough”) amplitude. In seismology <i>ground motion</i> amplitudes are usually measured in nanometers ( $10^{-9}$ m) or micrometers ( $10^{-6}$ m). |
| <b>amplitude response</b>                 | In general, the complex <i>frequency response</i> (e.g., calculated as <i>Fourier transform</i> of the output <i>signal</i> divided by that of the input signal) of a system. Specifically, the frequency-dependent amplification and phase response of <i>ground motion</i> by a <i>seismograph</i> , a site, a building etc., depending on their eigenoscillation and <i>attenuation</i> properties (for <i>seismographs</i> see Chapters 4 and 5 and for <i>site response</i> Chapter 14).                          |
| <b>analog-to-digital converter</b>        | An electronic device that converts a voltage produced by a sensor to digital values by applying specific digitization rates depending on the frequency content of the original signal.                                                                                                                                                                                                                                                                                                                                 |
